JOHN KING, M. D.,

In the Clerk's Office of the District Court of the United States for the Southern District of Ohio.

P R E F A C E.

THE present work has been prepared in accordance with the request of numerous practitioners who, when students, attended the author's lectures upon the Treatment of Chronic Diseases, in the lecture hall of the Eclectic Medical Institute of Cincinnati. In it, the author has endeavored to present the various subjects treated upon, in such a manner, that the student as well as the practitioner may become fully posted as regards the causes, symptoms, diagnosis, pathology, and most successful treatment of Chronic Diseases up to the present period. In the present work the term "Chronic Diseases" includes those maladies, functional or organic, whether of long standing or not, in which no active inflammatory symptoms are present.

Notwithstanding the great prevalence of chronic maladies, and the frequency with which physicians are called upon to treat them, it is surprising that but few works have been published upon the subject, and those of a meager and unsatisfactory character; indeed, there is no single work extant that the author knows of, in any language, that is wholly devoted to the consideration of this class of diseases,—the material has existed, but it has been in loose and scattered portions. The difficulty of understanding, and well understanding these diseases, the inefficiency of the treatment heretofore commonly pursued by medical men, and the apparent aversion generally manifested by them relative to attending patients laboring under such maladies, an aversion based, probably, upon their unsucess in the treatment thereof, and upon the want of confidence in their remedies so frequently displayed by such patients, may, perhaps, be among the principal causes why this class of diseases has been so sparsely touched upon by medical writers. Indeed, so slight has been the attention bestowed upon the treatment of chronic maladies by practitioners generally, that it has been by no means a matter of infrequency for a patient so afflicted not only to have been unsuccessfully treated by a number of physicians, consecutively consulted, but also to have received as many names for his malady as there were practitioners consulted.

Another reason why medical men, as a general rule, have been so indifferent

to the treatment of chronic diseases is, undoubtedly, because there has been no text work, no work of authority wholly devoted to this subject, which they could readily obtain; and to have procured all the monographs, journals, books, etc., in which this subject is referred to and discussed, would require an outlay of several hundreds of dollars. The present volume is designed to fill up this hiatus in the literature of that medical school to which the author has the honor of belonging. And although not free from imperfections, it is hoped that its errors and omissions will not be of such a character as to lessen its usefulness in a *practical point of view*, and that they will be indulgently looked upon by the profession.

In Parts I and II, the matters treated upon are presented in a somewhat popular style, with the hope that it may prove serviceable to extra-professional persons who may have an opportunity of perusing said Parts. The author is fully aware that in these, as well as in other parts of the work, he has presented heterodoxical, or mere hypothetical views relative to certain points,—but these are his own views at the present time, and he gives them for what they are worth,—it remains for a future more thorough knowledge, as well as accurate investigations and experience, based upon such enlarged and more perfect knowledge, to determine their correctness or falsity.

In Part III, devoted to Chronic Diseases, he has treated upon them in the order of the several systems of the human body, (excluding the so-called specialties of the Eye, Ear, and Prostate Gland, the maladies of which organs are considered under separate heads in Part IV), as being the more satisfactory method of arrangement for the medical man, and he has endeavored to render the description, etc., of each disease as clear, as full, and as complete as possible, consistent with the limits of the work. Those diseases to which the female sex alone is liable, have not been treated upon in the present work, they will be found in the author's work on Diseases of Women, and it would be a mere repetition to reproduce them here.

But, in practice, it must not be expected to encounter single diseases alone, nor to find single organs only affected; experience has taught us that chronic diseases not only exist as simple lesions, but also that they are very frequently complicated in various ways. In this work these complications have not been treated upon further than by referring to the probability and possibility of their presence when describing the simple lesions of only one organ or part; to do more than this, successfully, would require numerous volumes. The general principles of treatment for each disease and each diseased organ are all that can be satisfactorily given in a work like the present, and with these every medical man should be conversant; the important art for him to

learn subsequently, is to modify these principles and adapt them to the ever-changing symptoms of both single and associated maladies. It is in successfully doing this that the physician displays his judgment, his skill, and his well-grounded knowledge in the several departments of his profession.

The Tables prepared by the author for Part V, will, it is hoped, prove useful to the chronist as well as to the general practitioner, and also to those engaged in microscopie investigations in which the French weights and measures, now legalized by our United States Congress, are frequently employed.—The Index is arranged in accordance with the general disposition of the subjects treated upon, and will be found full and complete.—It is proper to state here, that where the names of compounds are given throughout the work, and not the formula, the latter will be found in the author's American Dispensatory.—As to the doses of medicines, although frequently specified, they will require to be varied according to individual susceptibilities, influences, constitutions and circumstances; the careful practitioner will, in all cases, be guided by these several conditions in his administration of them, and never by any exclusive or arbitrary rules.

The aim of the author has been not so much to present a wholly original work, as one of *practical utility* to the great mass of practitioners, its material being derived from every reliable source; and although a very large amount of original matter is contained in its pages, together with new and original methods of treatment, as well as several valuable remedial preparations which he now makes known for the first time, and also the several Tables in the latter part of the work, yet he desires it to be distinctly understood that no originality is claimed for the work, which must be regarded simply as a compilation.—The principal portion of the treatment named under the respective diseases, is such as the author has found successful in his own practice, and which he has been in the habit of pursuing for many years past.

Much valuable material, especially relating to the *history* and *description* of diseases, as well as their *pathology*, has been selected from various eminent European writers, especially from the English, French and German, and which is thus brought before the profession of this country in an American form, and which it might have been difficult for our practitioners to otherwise obtain except at considerable outlay. The author does not, therefore, hesitate to acknowledge himself under very great indebtedness to the labors of others, whose names have in several instances been omitted in the text, and whose language is frequently given in full, preferring it to any abridgements thereof, or transpositions of his own. Especially is he under great obligations to Prof. Brown-Sequard, and the other eminent medical writers, who have so

kindly permitted him to freely make use of their publications. Truly great minds are ever magnanimous; they possess no unhealthy prejudices, nor discourtesy toward those who honestly differ from them in opinion,—the welfare of the human family and the spread of truth alone actuates them.

The following is a list of the principal authors referred to above, whose writings have been selected and compiled from, more especially in the *history*, *description*, and *pathology* of the various maladies treated upon, in the present work, and to several of whom I am under the greatest indebtedness for an abundance of most valuable and highly practical matter:—Adams, Alibert, Althaus, Anderson, Andral, Aran, Baillie, Barclay, Barlow, Basham, Basereau, Bateman, Bayle, Bazin, Beale, Becquerel, Bell, Bellingham, Bence-Jones, Bennett, Beraud, Biett, Billard, Bird, Bowman, Bright, Brinton, Brodie, Brown-Sequard, Budd, Busk, Caudmont, Cazenave, Chambers, Christison, Civiale, Cooper, A. Cooper, Copeland, Cruveilhier, Czermak, Davies, Desmarres, R. Dick, Dickinson, Dixon, Dobell, Donders, Duchenne, C. H. Ehrmann, Erichsen, Fischer, Fourcault, Fournier, Frerichs, Fuller, Garrod, Gibb, Giraud-Teulon, Von Græfe, Graves, Green, Habershon, Hardy, Hassall, Hasse, Haygarth, Hebra, Henle, Hogg, Hope, Horion, Hunt, Hunter, Jenner, Johnson, Jones, Knapp, von der Kolk, Kramer, Laennec, Latham, Laurence, Lawrence, Laycock, Leared, Lees, Lehman, H. Lobb, Louis, Leroy (d'Etiolles), Mackenzie, E. Martin, Mercier, Neubauer, Neucourt, Oppler, Ormerod, Paget, Parks, Pavy, Perls, Prout, Quain, Racle, Radcliffe, Rayer, Rees, Reynolds, B. W. Richardson, Roberts, Robin and Verceil, Rokistansky, Romberg, Rosenstein, Ryland, H. H. Salter, Seegen, Sieveking, Simon, Skae, Skoda, Smith, E. Smith, Startin, Stokes, Tanner, Thomas, H. Thompson, T. Thompson, Thudicum, Todd, Toynbee, Triquet, von Troltsch, Trousseau, Velpeau, Vidal, Vogel, W. F. Wade, Walshe, Watson, Wecker, Wells, Wildo, S. Wilks, Willan, Willis, Wilson, Winslow, Zalesky, etc.

JOHN KING.

CINCINNATI, OHIO.

INTRODUCTORY REMARKS.

HYGIENE.*

PREVIOUS to entering upon a description of the medicinal treatment which I have found to be the most successful in palliating or curing chronic diseases, it may be proper to refer to the principal Hygienic measures which should always be associated with such treatment. Because, however valuable a medicine may be in effecting a removal of disease, it is a well-known fact, that its beneficial influences are rendered more prompt and permanent when its employment is associated with proper hygienic measures; and also, that in a great number of cases, a neglect of these measures is certain to be accompanied with a diminution, or entire want of efficacy of the therapeutical treatment. Indeed, how frequently do we meet with persons laboring under some form of chronic disease, who, having lost all confidence in physic and physicians, are, nevertheless, enabled to palliate their worst symptoms, and even attain and enjoy an apparent state of health, by rigidly observing certain hygienic rules? And, from an experience and observation of thirty odd years, I can now conscientiously say, that although there are many maladies in which medicines and medicinal treatment can not be dispensed with, yet I am fully convinced that nearly, if not quite, one-half of the sicknesses which come under the care of medical men, could and ought to be cured solely

* Hereafter, when, in the description of the treatment of the various chronic diseases referred to in this work, "*attention to the skin, the bowels, the kidneys, diet, etc.*," is advised, it is intended that in these matters the physician be guided by the remarks upon these several points to be found under their appropriate heads in this Hygienic department of the work. An attention to the skin includes bathing once or twice every week, and the use of the spirit vapor bath, every one, two, or three weeks, as the strength and condition of the patient will permit.

by a recourse to hygiene, and the absolute avoidance of any of the articles of the *Materia Medica*. And it is, undoubtedly, to this fact, that certain schools or systems of medicine of the present day, in which but little if any medicine is prescribed, while the utmost attention is bestowed upon the hygienic department of patients, owe much of their success in the treatment of disease, and their consequent great popularity.

Physicians, therefore, who desire to treat chronic diseases successfully, must pay especial attention to the hygiene of their patients, adapting it to their diseases, their temperaments, their susceptibilities, ages, vital force, and other circumstances connected with them; each one according to his or her conditions, and success will crown the efforts of the medical man, in proportion to the skill and judgment manifested in the proper arrangement and adaptation of hygienic measures to each individual case.

"In all ages and among all nations, civilized, as well as those in a state of nature, the first and prominent desire of man has been to prolong his existence; and even at the present day, notwithstanding the eagerness and perseverance with which wealth and ephemeral pleasures are sought, the preservation of health and life occupies a conspicuous situation in the hearts of men. Health is of the first importance to the human family; what treasures can indemnify us for its loss? What is the nature of that life which is passed in pain and suffering? of what use can a diseased man be to his fellow-creatures, to his wife, to his children, to himself? What services can he render to his country? What undertakings can he attempt? The insensibility of the coffin is preferable to the bed of pain upon which so many unfortunate victims to human infirmities languish.—Nothing, then, is preferable to health, but to preserve it, or to recover it, we must observe nature; we must recognize that our ills are almost always our own work, and it will then be more easy for us to avoid them. To be enabled to do this we must understand ourselves thoroughly, must investigate our points of contact with everything surrounding us, calculate the effects of food and drink, the influence of the air we breathe, and of the several conditions of heat, cold, dryness, moisture, purity and impurity, and carefully observe all the relations of physical and moral objects, of the secretions and excretions, of labor and rest, of pains and pleasures, of tranquillity of mind, and of the passions which too often agitate it. The practice of this science is Hygiene, a wise and prudent government of life, which should be the constant object of men's thoughts, of the serious study of the learned, as it is essentially preservative. Hygiene is an import-

ant part of practical philosophy; without an attention to its precepts the duration of life is abridged. But we must not confound it with curative medicine, which, engaged in restoring health, seldom considers whether the means it employs are fatiguing to the organism, or whether the secret springs it calls into action will not soon succumb to the extreme tension which it imparts to them. On the contrary, hygiene, always a faithful companion of nature, seeks merely to assist her progress by encouraging her steps. It is aware that a small amount of force, may, as well as a complete exhaustion, precipitate the course of life; its practice, being certain and without danger, ought then to take the preference over curative medicine; which, at the most, gives us over to a kind of chance.

“The first author of hygienic science was Hippocrates; four centuries after him came Celsus, who only gave a better arrangement to the materials left by this great master. Galen, the Arabs, the school of Salernus, and the learned of the middle ages, have only repeated Hippocrates, with the addition of many subtleties to his simplicity of means.

“If it be possible, patients should choose, not the most popular physician, but the one who has the greatest success in curing disease, and who is philanthropic. It too often happens that the most popular physician has gained his popularity by intrigue and management, and not by professional success and merit,—while the skilful physician is hardly known. It is a lamentable fact, that the essential qualities of the greater part of physicians, at the present day, consist in great boastings, in ready replies, in minds ready to bend to all manner of persons, in making outside displays, in flattering all tastes, opinions, and passions, in making every effort to usurp all places and to supplant those who have honorably occupied them for a long time. Cabals and intrigues are the methods by which so many competitors triumph in securing patients.”—A physician should never be selected for his popularity, his style of dress, nor his style of living, for the chances frequently are that by so doing we court death. Let his success, and that alone, be the cause of having him at our bedside. Yet there are many shallow-brains in society who do not hesitate to assert that they would rather die in the hands of a popular, fashionable physician, than live under the treatment of one less popular and less fashionable.

No special rules of hygiene can be laid down for all to follow; general rules only can be given, and the application of these, their modifications, combinations, degrees, etc., will necessarily vary according to the sex, age, profession, temperament, circumstances

of life, country, national customs, society, and other conditions belonging to each individual, and which it is the duty of the physician to understand. The prolongation of life and the state of health are proportioned to the moderation of the acts and passions of man; temperance, cleanliness, frequent exercise, sobriety, gaiety, respiration of pure air, exposure to sunlight, traveling, frequent visits to the country, abstinence from spirituous liquors, moderation in labor, diet, pleasure, and rest; peace of mind, avoidance of strong sudden passions, especially anger, and a reserve in the use of internal medicines, are among the means of health and longevity.—“How many persons are there who suffer from wounded vanity, from disappointed ambition, from false expectations, from loss of property, from a tarnished reputation, etc.? Wounded vanity killed Racine, made Pope morose, Virgil hypochondriacal, Hogarth insane, and Swift imbecile; it assassinated Winckelman and Fourcroy. The passions are at once the motive of our actions and the scourge of life; while moderation is that of strength and wisdom.”

Man is not an isolated point in space, nor a being independent of everything around him; we must study him in the localities he inhabits; in the fluids which surround him; in his profession; in his social position; in the friends whom he frequents, and in the habits which he forms and which, each day, impart to him a new existence.

Each age has conditions and distinctions which are inherent to it; in passing through them man changes his proportions, not only in his stature, but also in the mutual relations of the organic systems, in the development of organs and viscera, in the importance and activity of their functions, in the character and the abundance of the products resulting from them; consequently, these changes occur in all that which constitutes the indications by which we may judge of the difference of temperaments.

TEMPERAMENTS.—Each individual possesses a constitution or certain physical conditions peculiar to himself; these have been classified into what are called TEMPERAMENTS. Although we may find many persons whose constitutions bear, as it were, a family resemblance, yet, it is seldom the case that two individuals are found possessing identical temperaments.

Every medical man should be well versed in the study of the temperaments, as it will not only aid him in understanding the influence of external causes in the formation and progress of diseases, but will assist him in his endeavors to modify this influence and to preserve or restore that equilibrium between organic move-

ments which constitutes the condition of health. The temperament, of itself, indicates a state of disproportion between the solids and fluids, a want of equilibrium between organs charged with the most important functions of life; and, by a very simple deduction, it results that persons having a well-marked temperament are predisposed to maladies, the development of which is more rare and proceeds more slowly among others who have not the same organization.

Various classifications of the temperaments have been made by physiologists at different eras; that of Dr. Thomas, of Paris, and Dr. Caldwell, of America, is undoubtedly more philosophical than any of the others, being based entirely upon the solids, or the development of certain organs, as the brain or cranium, chest or thorax, abdomen, and muscles. According to Prof. J. R. Buchanan, this classification embraces the following: "1. The **CEREBRAL** temperament, characterized by a predominant development of the brain, is a temperament of mild character, in which animal impulse is overruled by the higher sentiments and human faculties. This temperament in perfection is tranquil, intellectual, moderately excitable, and never violent. Unless combined with a liberal share of the muscular temperament, it manifests a tendency to tuberculous disease, and general debility. The disorders peculiar to it are not very violent in their character, but are quite liable to assume a typhoid aspect. Hence, blood-letting, and profuse evacuations are especially objectionable, as there is not the necessary vital force to recover from prostration.

"2. The **MUSCULAR** temperament, characterized by large limbs and powerful muscles, is a temperament of great vital force and endurance; scarcely ever attacked by tuberculous or scrofulous diseases, but quite liable to rheumatism and inflammatory fevers, with but little tendency to sink into the typhoid state.

"3. The **ABDOMINAL** temperament is characterized by general inefficiency and relaxation, and constitutes the lowest grade of humanity.

"4. The **THORACIC** temperament, indicated by a large thorax, including a large development of lungs and heart, is the most harmonious and active of these temperaments, indicating, as it does, active circulation and aeration of the blood, thereby producing general activity of mind and body. This temperament presents active phenomena in disease, responding readily to medicines, especially to stimulants, and is frequently defective in the functions of the abdominal viscera, the appetite and evacuations being moderate. The tendency is to excessive activity.

“Of these temperaments, the purely *Cephalic* is adapted to the life of a sedentary student, but unfit for vigorous action. The *Cephalo-thoracic*, a compound of the Cephalic and Thoracic, is adapted both to study and to action, but especially to oratory and to social intercourse. Combined with a sufficient amount of the *Muscular*, it produces the best temperament for greatness, adapting its possessor to the noblest achievements, and is also favorable to physical health and harmony.

“The pure *Thoracic* temperament produces active and brilliant qualities, but requires a sufficient amount of the *Cephalic*, to give wisdom and calmness, and a sufficient amount of the *Muscular*, to furnish the necessary strength and vital stamina.

“The *Muscular* temperament alone, produces an athletic form and animal coarseness suitable to the prize-fighter, or the mercenary soldier, but unfit for any elevated or refined existence. The proper use of the Muscular temperament is to combine with the higher temperaments, and give them the necessary physical power and vitality.

“The *Thoracico-muscular* temperament possesses the highest degree of activity and force which the human constitution can manifest.—The *Musculo-cephalic* temperament is one of great power and intelligence, and endurance, but moderately excitable, resembling very nearly what has been called the *Bilious*.—The *Musculo-abdominal* temperament is coarse, sluggish, and powerful when roused. The character is gross, sensual, passionate, and unrefined. It corresponds with the inferior specimens of what is called the *Sanguine-lymphatic*.—The *Cephalo-abdominal* temperament is characteristic of infancy, as the brain and abdomen are then relatively large, while the chest and muscles are small. As we advance in life, the Cephalo-abdominal temperament diminishes, and the Thoracico-muscular increases, the chest and muscles of the adult being much more largely developed in proportion, than those of the infant, while the abdominal organs are relatively much smaller. The liver, especially, diminishes in proportional development, and a torpid hepatic condition frequently occurs. The temperament of woman is intermediate between that of the adult man and that of the infant, having proportionably more than man of the Cephalo-abdominal in comparison with the Thoracic and Muscular.”

The old classification of the temperaments, based upon the supposed properties of the fluids of the body, as, of the blood, the bile, the nervous fluid, and the lymph, is, however, more generally recognized among medical men than the preceding one; and, although not perfect nor entirely correct, as it bears considerable

analogy to the foregoing one, just glanced at, I will briefly refer to it. According to this classification, we have the following :

1. The SANGUINE TEMPERAMENT, in some respects resembles the Thoracic ; it is recognized by vigorous physical development, active circulation, passions, and appetites, with a moderate degree of perseverance, intensity, and depth of character, and a complexion generally somewhat florid, and requires for its manifestation a good share of the *basilar organs*. It must be remembered, however, that a plethoric abundance of blood does not produce the characteristics of this temperament.

Vital motion is determined by the intimate and reciprocal action of the Sanguine and Nervous temperaments; nearly all authors have considered the fundamental type resulting from this combination as the most favorable physical condition for health and happiness,—but the descriptions, which they have embellished, have not always agreed with the realities of experience, and are only agreeable fictions. Health results from the equilibrium which must exist between the organic solids and fluids, and the predominance of the sanguine system, of itself indicates a tendency to the destruction of this equilibrium. It will suffice to trace the history of diseases, to become convinced that an abundance of blood is one of the organic conditions the most prejudicial to health. Hippocrates remarked, that the highest degree of athletic force bordered upon disease; this truth is especially applicable to the eminently sanguine constitution.

However, in childhood, this organic disposition announces strength, and coincides with the development of all the organs. It is hardly observed until near the period of puberty, when it increases as age advances, and at the fortieth or fiftieth year it attains its maximum of development, after which period it gradually decreases. In old age, the organic predominances cease or diminish, the sexes even lose a part of their attributes, and resemble each other in the uniformity of their tastes, the indifference of their desires, and the tardiness of their motions as well as of their sensations.

The physical and moral characters which many modern physicians have attributed to the sanguine temperament, following the example of the ancients, are, in part, those of childhood. One author says: “The ancients observed that men of middling stature and plumpness, with well-proportioned limbs, bright eyes, brown hair, a soft and pliant skin, a quick and undulating pulse, free movements, bold and determined, but without violence, enjoy a similar freedom, and a similar liberty in the internal operations of

their minds; that their affections, like their physiognomy, being amiable and cheerful, render them men of pleasure and agreeable companions." Further on, he adds, "Their moral maladies, their passions, their vexations, are not deeply seated; their passions are strong, instantaneous, sometimes impetuous, but are soon calmed and extinguished. . . . They are fitted for mental labors; but whatever requires great fortitude, deep thought, much care, and perseverance, will not suit them; they are entirely incapable of them."

Such is the agreeable, but somewhat imaginary description, which has been given of the sanguine temperament; we may observe that it mingles some traits peculiar to a predominance of the vascular system, with the general attributes of childhood and with acts which ought to belong to a happy organization of the brain. In this manner authors copy from each other, allowing their imagination to have free scope instead of studying nature.

A person of sanguine temperament may be of great height, medium, or small, have brown hair, eyebrows of a black or any other color; he may be stout, lean, or have a medium plumpness; all these external characters are deceitful. The man whose constitution is not accidentally sanguine has a large chest, the complexion naturally florid, and the veins prominent, especially when he is not very corpulent; the movements of the heart are energetic, the pulse is almost always strong and developed; he is, at times, subject to hemorrhages, to giddiness, to heaviness of the head, and has frequent need of depletion by purgatives, sudorifics, etc. These are the characters of this temperament. But we find other persons whose constitution is weak, complexion pale, with but small development of the chest, blood-vessels, and muscles, who present, nevertheless, at greater or less intervals, symptoms of plethora, of hemorrhages, of congestions, etc., which require the same remedial means. These morbid dispositions must not be confounded with the characters which distinguish the constitution of sanguine persons in a normal state; for, with these, the lungs and the blood-vessels are not only well developed, but the fluid circulating in them is thick, coagulable, rich in fibrine, and especially in globules. A similar organization is a manifestation of strength.

But it must be recollected that the external appearances attributed to the sanguine often conceal the radical weakness of the lymphatic temperament. A florid complexion, dark and sparkling eyes, a soft and pliant skin, light-colored, brown or black hair, may be met with in a debilitated and anemic constitution. These external signs are then deceitful, and the most serious results may

follow untimely depletions among young persons possessing a like constitution.

A predominance of the sanguine temperament is often presented under the external forms attributed to the bilious and adipose temperaments of the ancients. Such men have a pale or yellowish complexion, large chest, strong and well-developed pulse, with evident plethoric tendencies; they readily support depletion, exercise, and physical labor. The prominence of the sub-cutaneous veins, the development of the muscles and of the nervous system, the abrupt forms of the osseous system, characterize this organic disposition, which has received the name of *bilious*, or *bilious-sanguine*.

The vascular system requires a remarkable preponderance over other organs, in adult age especially; in this age we more frequently meet with symptoms of plethora or fullness of blood. Observation has shown us that many very sanguine and very robust men can not pass beyond the middle age, and also that apoplexies and sudden deaths increase in frequency between the fortieth and fiftieth years. We must then, at this period of life, by a proper hygienical course, by active exercise, by attentions to the skin, bowels, and kidneys, diminish these fatal tendencies of nature.

To give an exact idea of the sanguine temperament, and to profitably observe its various phenomena and effects, it is not enough that we study it in its generic and abstract characters; we must study it in the particular cases, and in its several varieties. These varieties are very multiplied. If we refer them to the eventual modifications which certain systems of organs, or certain viscera, in particular, are capable of producing upon the effects of the sanguine predominance, we will observe that the lymphatic, nervous, and muscular systems, the liver, digestive apparatus, etc., by their secondary predominance, may alone modify the purely sanguine temperament, giving, as a consequence, varieties which may be called sanguine-lymphatic, sanguine-nervous, sanguine-muscular, sanguine-bilious, etc. Among these varieties, some are natural and some are acquired; the germ of some exists within us from birth; they become developed within us by virtue of an innate disposition, the nature of which is unknown, and independently of the circumstances surrounding us. Others, on the contrary, are purely accidental, being the result of deep-seated indispositions impressed upon one or several of our organs, or systems of organs, by the long-continued influence of the action of certain events to which we are exposed, as climate, regimen, exercises, passions, diseases, etc.

2. The BILIOUS TEMPERAMENT somewhat resembles the Musculo-

cephalic. It is attributed to a predominance of bile and large liver, but this is not strictly correct. This temperament is indicated by firmer fiber, and more rugged outlines, with greater hardihood, perseverance, and moral strength of character, than is present in the sanguine; it is due to the *upper occipital region*. It is evident that the special function of the liver, the only one which physiology is supposed to have positively verified, is relative to the secretions. There may undoubtedly exist an unknown relation between the yellow color of the skin, the latent activity of the liver, and the considerable energy of the nervous system, without our attributing to the former, phenomena which are evidently due to the action of the brain. It is, after all, to the functions of this organ that we must attribute the manifestation of intellectual faculties and moral qualities. In the animal series their development is strictly subordinate to that of the different parts of the brain, and not because of the size of the liver and the quantity of bile which it secretes. Persons said to have a bilious temperament are lively, fiery, quick, and impetuous in their movements; have absolute and exclusive affections, an unalterable will, and a remarkable development of intellectual faculties and moral qualities. The bilious man has a dark, brownish or yellowish complexion, firm, vigorous muscles, black hair, a hairy body, a thick beard, black, prominent, and bright eyes, elastic, hard, and quick pulse, and a severe and expressive physiognomy; he is impetuous, irascible, generous, ambitious, indefatigable in labor, but by paroxysms rather than with steadiness, is an insatiable eater, more from necessity of nutriment than from a fondness for the table, is domineering, brave, even to a contempt for life, jealous, though inconstant, and has an excessive energy of vitality. This temperament frequently predominates among men of talent, and is generally met with in combination with one or more of the other temperaments, which modify its effects according to their degree of development.

The diseases more common to this temperament are bilious fevers, diseases of the liver, spleen, stomach, and kidneys, unhealthy action of the skin and bowels, etc. A vegetable diet, proper use of acids, warm baths, injections, cheerful society, well-regulated sleep, etc., will tend to modify, or even prevent the symptoms to which the bilious temperament is liable.

3. The NERVOUS TEMPERAMENT somewhat resembles the Cephalothoracic. It is recognized by delicacy of fiber and complexion, ready intelligence, quick, excitable emotions and passions, with but moderate intensity and violence; there is a development of the

frontal and lateral regions of the head, which produces a quick, intelligent, sensitive, excitable, and rather unreliable character.

The nervous system is the motive power of the organs, and the regulator of their functions; it is the internal man, the true animal, concealed beneath organized envelops; without its action life is extinct, and the other organs form only inert masses. This system presents three principal divisions. The first is devoted to the functions of the life of relation, or animal life; the second, to those of organic, or internal life; and the third, to the life of the species. But this latter part of the sensory and motor system forms, by its predominance or activity, a particular temperament, which has been called the *erotic* or *genital*.

From a neglect of these divisions, the characters of the nervous temperament have not, heretofore, been traced with precision; a development of physical sensibility, or a considerable activity of that part of the exciter system designed for sensation, has, generally, been considered the indication of this temperament. But we may likewise apply the same designation to the energy of the apparatus of voluntary motion, in a word, to physical strength, when it is not accompanied with much development of the muscles. Women and children, particularly, present the first shade of the nervous temperament, as well as many inhabitants of southern countries; men, especially those who have been classed among the bilious, are distinguished by that energy indicating a preponderance of the nerves of motion over those of sensibility. However, these two shades may be blended, and form the true type of the nervous temperament.

It is important to remark that persons who present all the attributes of this temperament do not always have excitable viscera; indeed, we frequently meet with those of this character, who may take large doses of excitant remedies with impunity, and without causing any remarkable disturbance in the digestive functions; with these, organic irritation merely develops some nervous phenomena, but can not determine fever or inflammation. On the contrary, we find a lively excitability among individuals presenting the external characters of lymphatics; irritation of organs readily causes a derangement of their functions, and a well-marked febrile action. We may say then, in these cases, that the sensibility acts in the manner of a fluid, the complement of which is determined; it is the more abundant in certain canals, as it gradually diminishes in others. This view is not only a comparison, but it indicates a physiological fact.

The true nervous temperament, then, results from the develop-

ment or considerable activity of the nervous system of the life of relation; the two very distinct shades which it presents may be combined, or may exist separately among many persons. The development or the predominance of the apparatus of motion is characterized by an extreme energy of the motive power; it gives to men who are endowed with it the faculty of devoting themselves to all bodily exercises, and to continuous physical labors. If they are not so strong as athletes, they are more pliable, more active, and can more readily resist the fatigues of war. Courage is very often a gift bestowed upon them by nature; they will also be frequently endowed with a lively imagination and vehement passions. Sometimes they will be presented to us with the external characters of the sanguine temperament; at other times they will be seen with black hair, an expressive physiognomy, and a slightly-yellowish color of the skin, attributes belonging to the so-called bilious temperament; again, some may be met with having the deceptive forms of lymphatics, etc.

A predominance of the nervous apparatus of sensation is more especially observed in great cities and among civilized nations. Cultivation of the fine arts and literature unceasingly tends to excite this apparatus, and with it physical and moral sensibility. In this relation, who does not know the effects of music, of spectacles, of political commotions, of an existence constantly agitated by the passions? But woman is the most sensitive being; her education tends to increase the dispositions of nature; rest, intellectual labor, solitude, the reading of works which exalt the imagination, augment the mobility of the nervous system. From thence, those outbreaks of moral life, those nervous affections, so frequent in great cities,—those derangements of intellect and the calamities resulting from them. An exquisite sensibility is, then, the most prominent feature among nervous persons, whatever may be the forms they present. The villager devoted to physical labors has not this agitated life; she does not experience the same emotions, the same voluptuousness, the same mortifications, nor the same sufferings; her sensibility is exhausted, or at least considerably diminished by exercise and work. Indolence, solitude, a life of contemplation, have absolutely opposite effects.

A remarkable development of intellect and activity of the passions distinguishes many men whose general constitution is that of the sanguine, bilious, or lymphatic. A feeble body often encloses the most distinguished intellect; but the physical force is not always in opposition to the most noble and elevated faculties; and facts prove that these sublime faculties are due to the cerebral

organization. Man is necessarily an imperfect being; and it is seldom that all the nervous centers enjoy equal activity, or that he possesses this strong and harmonic organization, this activity of all the faculties, this power of all the movements; he ordinarily presents only partial predominances, which any one may study, and of which the physician, in the course of his observations, should carefully take note.

4. The LYMPHATIC TEMPERAMENT is produced by the development of the *frontal half of the head generally*, excepting the regions appropriated to the Nervous temperament. There are two forms of the Lymphatic temperament; the higher Lymphatic, due to development of the regions lying above, *between the frontal and occipital organs*, producing general calmness and contentment, and corresponding with the Cephalic; and the lower Lymphatic, due to development of the *anterior portion of the middle lobe of the brain*, producing indolence and languor, and corresponding with the abdominal. The Lymphatic temperament, therefore, in the aggregate may be considered equivalent to the Cephalo-abdominal.

This temperament may be united with the preceding, forming numerous intermediary shades. The lymphatic complexion is, however, especially characterized by serous plethora or polylymphism; it is particularly met with in marshy countries, along shores which are covered with water during a portion of each year, in countries containing immense forests, or in which the putrefaction of vegetable substances is favored by the habitual moisture of the soil. The aqueous vapor with which the air is saturated permeates within organized bodies, and occasions a general relaxation of the tissues. Paleness of the face, whiteness, softness, and inelasticity of the skin, very round forms, plumpness or corpulence, uniform habits, slowness of motion, want of liveliness in the sensations, moderate passions, inaptitude to support painful labors and long privations, are among the principal moral and physical characters of individuals and nations who live in countries where a constant moisture is present. A similar disposition is often the origin of the most serious affections; they are developed when this cause exerts its influence with great intensity, when deleterious effluvia add their action to that of the moisture. Under these circumstances, there appears to exist a tendency to dropsy and dissolution of the solids, and the blood is loaded with a great quantity of water or serosity. The enfeebled constitution presents a precocious deterioration and a premature old age. Scorbutus, visceral engorgements, the most obstinate autumnal fevers, the most serious putrid fevers, caries and loss of the teeth,

show that the surrounding causes have deeply altered the vital fluids and the constitution of man. Hippocrates has described the inhabitants on the shores of Phasis with that exactness which characterized this great observer. We observe that they take on lymphatic forms; they are of high stature, overloaded with plumpness; their articulations and their blood-vessels seem lost in an unhealthy fat; their whole body is pale, or rather the color of their skin somewhat resembles that of persons who have jaundice; the air which they respire being impure, hazy, and very moist, they have a harsh voice; finally, they are remarkable for the slowness of their movements, and for an almost absolute want of activity.

The surrounding causes of the lymphatic complexion, the external forms, and the special morbid changes which characterize it, differ, as we may see from the attributes of what has been termed the Cellular temperament; we can not confound these two organic dispositions in their most marked shades. The first is observed in the most unhealthy places, where there is constant moisture of the atmosphere, kept up by ponds and marshes, which promptly deteriorate the constitution of the inhabitants and singularly abridge their term of life. We can only free ourselves from the destructive influences of these morbid locations by abandoning them, and dwelling in mountains or upon elevated table-lands. In these unhealthy countries referred to, animals become fatter, less active and vigorous, than in dry and elevated places; and vegetables are often developed with rapidity, acquiring large dimensions, their tissues imbibing a very large quantity of moisture. Everything announces the deep-seated influence of the localities and the surrounding causes upon the constitution of living beings.

The scrofulous constitution, which appears to be only an augmentation of the lymphatic and cellular predominances, is often the result of the etiolation of the skin, of a prolonged sojourn in dark and moist habitations. In this morbid disposition the lymph and albumen prevail over the fibrin and blood globules. Badly-elaborated juices slowly circulate in the vessels, and have a tendency to continue in them. The attributes of this constitution differ according to the age and sex. With many young persons the features of the face are delicate, and the rosy hue of the cheeks agreeably contrasts with the remarkable whiteness of the skin. The large, prominent, and watery eyes give an extreme softness to the countenance; their color varies according to climate—blue predominating in the North, and black among the

lymphatics of warm countries. To the charms of beauty is often added endowments of the heart and mind, an exquisite sensibility, an unalterable patience, and a surprising resignation.

But the lymphatic constitution does not always present such attractive forms nor such valuable qualities. Frequently, among those who possess its principal characters, we observe the organ of intellect but little developed, and the nervous system in a languishing condition. The face is full and seems puffed up; the eye is inexpressive; the sides of the nose, the lips, and especially the upper one, are swollen; the extreme softness of the flesh, the clumsiness and doughiness of the limbs, and the dryness of the skin, frequently wrinkled or scaly, all indicate inactivity of the perspiration. The physical as well as the moral functions are only imperfectly carried on. At times, this want of activity begets apathy; and children are sometimes met with deprived of all sensibility. Forced marches, continued physical labor, the fatigues of war, are not suited to lymphatics; they soon become emaciated, requiring an abundance of nourishing animal diet to restore strength. Young soldiers of delicate and lymphatic constitutions rapidly succumb to fatigue and privations; they become emaciated, livid, limbs slim, body lank, and soon die in the hospitals. Such instances show how indispensable it is to know how to proportion the duration of the exercises, the march, and the corporeal labor to the physical force, the vital resistance, and the temperament.

The vital resistance is in direct ratio with the development and energy of the nervous system. It is moderate with the sanguine, still feebler with the lymphatic and the cellular; but it is very preponderating among those who, by a happy alliance, have the nervous and muscular forces united. The sanguine temperament does not produce prodigies, but its progress is regular, perhaps a little too monotonous. Lively and impetuous passions belong to the sanguine; peace and quiet to the lymphatic. The sanguine can command; the lymphatic can only obey.

Now, according to these considerations, it is easy to be convinced that the muscular or athletic organization is only an augmentation of the sanguine temperament. The hardened tissues or the bones, which distinguish lean men of high stature, has a great affinity with the cellular, the external attributes of which often conceal the energy of nervous subjects. Giants, for instance, who present the most prominent type of the sclerous condition (hardening of the tissues), can not be classed among lymphatics. In fact, with the first, gelatin and phosphate of lime predominate,

while with the latter, albumen and water are in excess in the organism. In these two conditions, weakness and want of resisting power are evidently produced by aneuria and anemia; in other words, by a predominance of the principles which receive vital action from those elements which alone can communicate it, the nervous and sanguine.

Tonics, strengthening measures, excitants, are proper for the lymphatic temperament, when in excess; it requires attentions to the skin, active perspirations, exercise regularly taken, a frequent but moderate use of wine and drinks which impart tonicity to the muscular fiber. Our aim should be to direct all our efforts so as to advance it toward the sanguine temperament. The varieties which the lymphatic temperament may present, relatively to its proportions with the other systems of the body, are one of the circumstances which exert an influence upon the physical and moral physiognomy of man. The lymphatic system is one of the parts the most liable to disease, and the diseases of which have a most profound and marked influence upon the general state of nutrition. We know that the greater part of cachectics have diseases of this system: coryza, ozæna, aphtha, scrofula, tabes mesenterica, leucorrhæa, dropsies, etc., are more frequent among lymphatics. All their maladies are of slight intensity, progress slowly, and are resolved with difficulty. This temperament is more common to children and females.

5. CELLULAR TEMPERAMENT. — The areolar or cellular tissue incloses the fatty tissue, and may be considered as the original or fundamental element of the organs. It forms the matrix or mass which surrounds the viscera, the peculiar envelops of the muscles, nerves, and blood-vessels, and gives a more or less thick layer beneath the skin, of which it forms the mucous body; by acquiring more density, it also constitutes serous membranes, and likewise forms the spongy substance of the villousities of mucous membranes.—However, this tissue, with the exception of absorption and exhalation, performs only a passive part in the economy; when it predominates, and the nervous and sanguine systems are feebly developed, the constitution of the person then acquires a very remarkable character for feebleness and inertia. This organic disposition differs from the lymphatic constitution, although these two states may be united by intermediate shades; but in the first the tissues are dry, so to speak, while in the second they have imbibed water or serous fluid. The one is especially observed in the country, in healthy locations, among individuals who exhaust themselves by corporeal labors, by profuse perspirations, and who

can not repair their losses by a substantial nourishment; the other, on the contrary, is met with in moist climates, among men who live in marshy places, in the midst of an atmosphere loaded with vapors or saturated with humidity.

When I commenced to study, in society, the external forms and the tendencies which organic predominances reveal, I was struck with the moral and physical inertia of some lean persons, of a medium height, sometimes small, yellowish complexion, black or any other colored hair, brown eyes, and slim limbs. I saw the principal attributes of the bilious temperament of the ancients, with the intellectual and moral dispositions of the lymphatics; their diseases being distinguished by a remarkable tardiness of organic movements and morbid sympathies. Profuse depletion promptly exhausted these individuals, and, as with lymphatics, the clot formed by the blood was not very distinct.—Debilitating causes, bad food, privation of light and open air, excessive labors, cause a predominance of the organic, by debilitating the nervous system, and exhausting the sanguine. This organic disposition may be hereditary or acquired, and is especially noticed among villagers and poor artisans, weavers, tailors, shoemakers, students, prisoners, and miners.

The whiteness, slightly yellowish, of the skin, the smallness of stature, the slenderness of the limbs, the habitual calm of the passions, the feeble development of the sanguine system, are indications of this temperament, which is frequently seen among those who work in sandstone.

The above classification of the temperaments may prove useful to the physician; for, in having an exact knowledge of the organization of man considered in its relations with external agents, we may demonstrate that these agents must determine upon it different effects, according to the original or acquired predominances which may exist. Thus, very lively physical or moral impressions excite a great perturbation in the sensitive system, and we may then observe various nervous symptoms developed, as well as diseases of opposite characters. Chronic inflammations and organic lesions are often presented to the physician along with the symptoms of the original affections. The sanguine, under the same influences, are more inclined to active inflammations, congestions, and active hemorrhages. As to passive hemorrhages, and diseases common to deep-seated debility, they are more frequent among subjects whose blood is watery and impoverished by the diminution of its globules and its fibrine. Lymphatics are often affected with chronic engorgements, dropsies, serofula, leucocythemia, and

tuberculous affections. The latter may, undoubtedly, be developed among persons having other organic predominances, but they are infinitely more common among lymphatics predisposed to scrofula. A simple contusion often suffices to arrest the sluggish course of the lymph or of the albumen in the lymphatic vessels and in the ganglions. Persons of a lymphatic constitution, who fall upon or bruise the knee, the hip, or the elbow, are more apt to have white swellings or synovitis; they may also have lateral or angular curvature of the spine from a blow on the back, or consumption from a prolonged pulmonary catarrh.

The external forms of man are variable, and assume infinite shades; the fundamental types are rarely presented, in nature, with all the attributes which distinguishes them in our artificial classifications. Many persons remain out of these classifications, and have no temperament, in the vicious acceptation given to this word; for, with them, no apparatus or system of organs appears to have any remarkable predominance. Hence, an accurate study of the temperaments and their numerous combinations is an important matter for the physician.

“If the physical constitution always corresponded to our natural character and tendencies, the development of the brain would be, in all cases, a true indication of the temperament; but, as our modes of life and circumstances are often widely different from our natural inclinations and capacities, it is necessary to look to the general appearance and constitution, as well as to the cerebral development.”

Man can not, as a general rule, change the character of his temperament; it is a predisposition born with him, and which time alone may modify. But he may correct it when in excess, and prevent its ravages, by adopting the hygienic course which experience has ascertained to be the best. He may modify his temperament, and even, to some extent, produce, in some instances, a new or mixed temperament, by a change of education, habits, diet, exercise, etc. According to the tendency of certain faculties, we may dispose man, as far as his original constitution will permit, and within the limits of his special temperament, to undergo modifications the most favorable to his preservation and happiness.

All inclinations, all errors, all crimes, and all virtues, are not invariably the fruits of education, habits, or examples, nor always subordinate to positions and circumstances. And every man ought, therefore, to thoroughly study his own temperament.

GENERAL REMARKS ON HYGIENE.

Experience attests that man ought to live one hundred and thirty or one hundred and forty years. Instances of such longevity are rare, it is true; but, with the aid of science, they may become more and more frequent, and that which has been the exception may become the rule. The learned Hufeland declares that there is no impropriety in saying that the life of man ought to continue for two centuries, and which opinion is in perfect accordance with the relation which exists between the duration of growth and that of life. We know that an animal lives seven or eight times as long as is required for it to attain its full growth; now man arrives at his growth in twenty years, and being superior to animals, the duration of his life ought, at least, to extend to two hundred years.

It is less the perfection of a machine than the use one makes of it that determines its destruction or duration. Many delicate and feeble women reach an advanced age, while many young men, in the plenitude of their strength, fall under the attacks of disease.

What is it, then, that occasions death before man has lived one-fourth of his allotted period? It is his ignorance of, or inattention to, the laws of nature. Acrid and burning substances, as pepper, cloves, vanilla, mustard, vinegar, strong herbs, tea, coffee, and fermented and aromatic drinks, are freely made use of as common articles of diet; and an advanced civilization has made them objects of the first necessity; it has multiplied them and combined them in numerous ways to provoke appetite and to excite sensuality. Nay, physicians not only tolerate them, but even have advised them. Not only is the use of alimentary *excitants* abused, but strong alcoholic drinks are used nearly as freely and as common as water; the hair is excited and injured by oils and washes, the eyes by paints, the skin by cosmetics; we are purged; we are bled; we turn night into day; we transform love into pleasure; and we employ all means of living fast, of weakening the moral energy and of destroying health.

Some pass their nights in the ball-room, or at play, in confined places, or where the atmosphere is highly vitiated by dust, by the combustion of lamps, as well as by the emanations from a more or less diseased assembly. Others, carried away by their passions, exhaust themselves and destroy their intellect by other excesses; a third party pass most of their time at the table, making a god of their stomach, which they surcharge even to apoplexy; while a

fourth enfeeble themselves by sleep, inaction, prolonged warm baths, wearing flannel in summer, etc.; some give themselves up to anger, envy, hatred, jealousy; others enervate themselves by the use of tobacco, and other articles destructive of nervous force; each one acts against his own welfare, by placing himself in open opposition to his health, and employing the most capable means of consuming his already short and sorrowful life.

Although the city has many advantages over the country, as the greater readiness of procuring the necessary agents and means for the sick, as well as the ability of procuring articles not to be had in the country, yet, were it possible for us to view, simultaneously and collectively, all the miasms, all the putrid emanations, all the corruptions of air, water, and food, all the diseases and contagious, all the sources of suffering, all the antagonisms, all the rivalry of interests and ambitions, all the egotisms, all the hypocrisies, all the agitations, and all that renders life so feverish, so wretched, and so short, in great cities, on the one hand; and on the other, the pure air, favorable sky, healthy nature, peace and contentment of the country, there are very few persons who would consent to live in the former twenty-four hours.

Nature, always true to herself, promptly warns us of the danger of injurious habits, by the disagreeable impressions we experience upon commencing them. Who is able to pass the first night at a ball without being extremely fatigued, or feeling a troublesome torpor? Who can accustom himself to snuff, chew, or smoke tobacco, to use strong drinks, to eat pepper and mustard, without first suffering more or less indisposition? Who can drink for the first time, and with pleasure, a cup of tea or coffee without sugar? Where is the robust man of the country who will be able to comply with the usages of city life without becoming sick? It is, then, only the instinct of imitation, the habit contracted in youth, or the necessity of yielding to fashion, which has led us to use these hurtful means; true, habit terminates by becoming a necessity—we then find pleasure in their use, we employ them in excess, and a host of diseases and infirmities soon overtake us as a punishment for these infractions of the laws of health.

The ancients were ignorant of the use of the greater part of these means which blast and destroy the energy of both soul and body; they were not acquainted with tea, coffee, tobacco, nor any of the excitants of the nervous system; their only fermented drink was wine, which they always mixed with considerable water; thus their diseases were few and simple, and their manners and physical constitutions were better than ours.

We are far from desiring a return to these days of patriarchal simplicity, or to this Pythagorean diet so opposite to our present condition, our manners, and our climate; the complicated organization of man requires a variety of nourishing and restorative aliments. An incomplete diet only sustains a part of the organs, and if it be prolonged, other organs will be injured. But will our meats be less savory when their natural qualities have not been destroyed by aromatics? Will our digestion be less effective, when it is the work of nature instead of that of excitants? Will our existence be less agreeable, when we disengage ourselves from everything that may injure or shorten it? If we do not experience those tumultuous pleasures, those insensate joys, those consuming passions, which torment the multitude, we will no longer have their low spirits, their griefs, anguish, distates for life, nor the diseases which consume them. On the contrary, we will possess vigor, health; we will experience pure pleasures, noble emotions, elevation of soul, power of mind, friendship, and devotion; qualities which were so common with the ancients, but are so rare with us. Life is a treasure in our hands; it depends upon ourselves to preserve it, or to quickly consume it. A long life, exempt from infirmities, is generally the price of a simple and natural course of regimen.

The mind, also, has its necessities, and the more it is cultivated the greater and more numerous become these necessities. Thus, assemblies, diversions, recreations, the fine arts, music, everything which responds to our legitimate aspirations without injury to the tranquil mind or to the health, is not prohibited; Hygiene, like morality, only condemns errors and excesses.

We can not shun death, but it is easy to extend the bounds of life. It is better to prevent disease than to cure it. We should love life without fearing death. To fear death is never to enjoy life, but to be always dying; it is more frightful to be unceasingly anticipating it than to receive it. All somber and melancholy ideas and thoughts are inimical to health and longevity.

Man is a two-fold being, moral and physical; he is so well constituted that harmony reigns between his two existences. A derangement of one almost always effects that of the other. Like the course of the year, man has his four seasons. In his spring-time there is superabundance, and in his winter there is privation; in the one he commences, and is not perfect; in the other he is completed, and is in penury; and in both he requires the same management and watchfulness. In both of the extremities of life man is weak and unsteady. Old men should receive the same

cares as children; we can not be too lavish with our attentions to the old age of him who was all profusion to our infancy. Shower upon him comforts and diversions, for old age has especial need of them, and has, also, more than infancy, the remembrance of them. Woman sustains and guides the first steps of man, and at the close of his career, we still find the tender and delicate cares of woman.

The destinies of each sex are the consequences of their physical constitution. These differences between men and women, as regards health, indicate upon what principles the direction of their physical, intellectual and moral education should be based.

Woman, being in general weaker than man, ought to guard herself more closely, for excesses will prove more fatal to her. The whiteness and softness of her complexion, and the beauty of her form, are due to the relaxation of her cellular tissue, which relaxation should impress upon her how much she has to fear from the influence of the seasons, variations of atmosphere, etc.

Nature, in imposing upon females the great and painful functions of maternity, seems to have desired to free young women from the fatigue of abstract things, of severe studies, of serious occupations which exercise the memory only at the expense of the judgment. Their instruction should not commence until at the eighth year, and should continue to twenty; then the education of teachers should cease, and that of the world commence. The violence to which the former make nature submit is never but imperfectly recovered from. Few talented women embellish the days of their husbands and children.

Among children, growth is the exclusive aim of nature; the organs of nutrition and of the digestive apparatus should occupy our attention—we may almost always augment the action of glands and lymphatic vessels by tonics. The cradle-life of the infant claims all our solicitude; mothers should carefully govern their conduct toward them, because upon their cares and attentions will depend the future existence of the being to whom they have given life. The constitutional differences of infants are less apparent the first months of their existence; the lymphatic system generally predominates over all the other vascular systems, and this predominance is especially marked in the cellular tissue; the amount of fluids are also in greater relative proportion than the solids. Let them breathe a pure air; do not confine them in tight swaddling clothes, which so painfully compress their delicate limbs. Be not too anxious to procure a too hasty development of their organs, for it will produce the same effect upon them as the sap produces on flowers, which, blooming before their time, are ephemeral,

colorless, and inodorous. Children have no past, no future; but happier than adults, they enjoy the present. They should be carefully kept from premature studies and too sedentary occupations; we should not endeavor to hasten the development of their intellectual faculties, but rather fear to make prodigies of them; for the phenomenon of ten years is almost always a man of mediocrity at twenty, and a stupid being at forty. The first study is to *make sure of their existence*; the first occupation to *strengthen their physical force*. Health is an absolute necessity; Latin, Greek, arithmetic, music, drawing, etc., are only relative necessities. A little less Latin, Greek, etc., but a great deal more health. We should not, then, consider as mere accessories the hygienic cares necessary to preserve health and longevity; for we must know that physical education influences the mental, and too prolonged labor or study, useless severities, revolting punishments, tend to humiliate and injure the mental advance of children. Interrogate those young pupils whose rapid instruction has not cost them a single tear, and one will be astonished to see in them, united to nobleness of mind, to excellent qualities of heart, a vigor of body and development of intellectual faculties. The whole secret consists in exciting the mind by strengthening their temperament by means of moderate exercise and agreeable recreations. But if a rigid discipline be pursued, paralyzing their development through fear and terror; if their adolescence be crushed with severities, constantly revived, we will soon see the roses fade from their cheeks, and sprightliness yield to sullen stupidity. If we desire to perpetuate in them good health, free mind, uniformly agreeable temper, and a happy nature, we must never forget the influence of hygiene upon their physical and moral education.

DIET.

The continual action of the composition and decomposition which constitutes nutrition is observed in the economy from birth to death; living bodies unceasingly experience material losses by the exercise of the functions; respiration replaces the air and heat which are disengaged; digestion repairs the losses of water and solid matters by means of animal and vegetable substances. But that this double and indispensable action may be effected, man and superior animals require a varied diet, without which they become feeble, waste away and die. Gelatin, albumen, fibrin, white bread, taken alone, for a given time, are not sufficient to overcome weakness of the organs nor to sustain vital action. Tiedemann and Gmelin having endeavored to nourish geese with sugar, gum,

and starch, along with water and pure quartz sand, these birds gradually weakened and soon died. The goose that had been fed upon the gum died upon the sixteenth day; that which had taken sugar, on the twenty-second, and that which had taken starch, on the twenty-sixth. Another, fed with a substance containing a large quantity of azote, and a sufficient amount of white of egg, expired at the end of forty-six days. Magendie submitted two dogs; the one to sugar and distilled water, and the other to a very white bread of a superior quality, containing considerable fecula and gluten, a well azotised substance, and they both died; while other dogs who ate exclusively soldier-bread, preserved their health and strength. This last article is distinguished from other bread by the bran it contains, and ought consequently to be preferred for soldiers and persons who are deprived of meats and other nourishing articles which constitute the variety necessary to life. A diet of sugar and water alone will not sustain life for any great length of time.

Animal substances are more nutritive than the tissues of vegetables; they contain, in a small volume, a greater number of elements fit to repair the incessant losses of the system, and leave a less quantity of unhealthy residuum. And as vegetable substances require to undergo a longer elaboration than animal, we find that, for this purpose, the digestive canal of herbivorous animals is much longer than that of carnivorous. Preference is generally given to the flesh of herbivorous animals, although that of the carnivorous is said to be fully as pleasant and nutritious. It is stated that the flesh of the cat is not inferior to that of the rabbit; in Africa the meat from a lion is much sought after, and that of the wolf is as savory as that of the deer. After the mammifers, come birds and fish.

Animal food varies in its reparative influences according to the kind, age, and part of the animal, the brain being more tender and nutritious, and more easy of digestion than the muscles, etc.

The more azote, albumen, and fecula, vegetable substances contain, the more nutritive are they; and among these we must comprise the cereal grains, leguminous plants, and the seeds of some bulbous plants. The soups made from these roots and grains may be usefully associated to strengthen exhausted subjects. Gum, sugar, starch, fat oils, have not the same virtues as the products of the cereals; containing no azote, they are not sufficient to support life.

Vegetable diet is not so favorable to weak persons as animal, especially to lymphatics, and those laboring under rickets, scrof-

ula, phthisis, and chronic morbid conditions of the albumen or albuminous tissues. The tribes of India who live upon milk and vegetables, and who follow a peaceable and unemployed life are more frequently attacked with leprosy than the Sicks, who, living in the same climate, make use of pork and lead an active life. Meats, then, ought to form the basis of diet for persons subject to the above named diseases, for they cause the fibrin and blood globules to predominate over the water, lymph, and albumen of the system. We can not introduce too much fibrin into the economy of these persons, nor enough of the elements proper to change the condition of the blood; and for this reason, the roasted meats of adult animals are preferable. It must be recollected that I am here considering the especial benefit only of the *physical system* when under morbid conditions—conditions which are frequently the result of an improper employment of the very diet I am now advising.

The quantity, quality, and manner of taking diet is a most important item in the treatment of chronic diseases, being, in a major part of them, of more essential service to the invalid than even his medicine. With regard to the quantity, enough should be eaten to barely satisfy the appetite, when nothing contraindicates; beyond this, is highly improper, even for those in health. As a general rule, in these diseases, all fat and greasy kinds of food, all acids, and whatever acidifies upon the stomach, must invariably be avoided, not only because they will prove injurious to the stomach, but also because they are apt to interfere with the medicines administered, preventing their remedial action. Tea, coffee, hot drinks, and liquors must not be used, except under certain circumstances and conditions to be determined by the physician; and among persons who are subject to a white coat on the tongue, to flatulency, or acid stomach, *milk* must be prohibited; though it may be proper to state that with some persons having the above symptoms, milk, milk and water, milk and lime-water, and cream, will be found quite digestive and nutritious. It is very difficult to particularize all the articles of food and drink that may be used, as many of those which are perfectly proper and quite healthful with one class of persons, would produce much derangement and injury with others. As a general rule, patients should eat moderately of *nourishing food, which is easy of digestion, and sits well upon the stomach, without causing distress, burning, heaviness, acidity, flatulency, or constipation, and which can not decompose the medicines administered, nor neutralize their sanative effects*; and in certain diseases where it would be improper to irritate or inflame diseased organs, everything must be avoided that tends to derange the stomach and

wels, to overtax the digestive powers, or to over excite the circulation.

The physician must attend to certain symptoms while regulating the diet of his patient; thus, a weak and irritable condition of the stomach may prevent the patient from employing a strengthening alimentation,—in this case, the debility may be overcome by a proper use of light wine taken with the meal, or by the use of certain bitter tonics for an hour or so previous to and following each meal; if there is great irritability of the stomach, it must be lessened by mucilages, anodynes, and counter-irritants to the epigastrium; if great acidity is present, lime-water may be taken with the meal, or some alkaline solution, bearing in mind, however, that a long continued use of alkalies contributes to debilitate the coats of the stomach, and that the acidity, being the result of weakness, is only temporarily allayed by articles of this class—a permanent removal of it must be effected by tonics, etc.; flatulency may be removed by the use of ginger, etc., combined with the food; and constipation, by the use of bran bread, corn-meal, figs, stewed fruits, etc., where there is no contraindication to their employment. Should a morbid increase of appetite be present, gentle nauseants will frequently remove it, especially when given just before each meal.

During a meal, little or no fluid of any kind should be drank, as it distends the stomach, dilutes the gastric juice, impairing its digestive solvency, and thereby increasing the tendency to disease. And when we take drink during or shortly after a meal, it should not be too cold nor too hot, but moderately warm; because heat being necessary to digestion, the cold beverage arrests the digestive process, causing the food to remain undigested in the stomach, often for several hours, thus producing dyspepsia, obstructions, etc.; and if the drink be too hot, the stomach will be too much stimulated, from which, when reaction takes place, results debility and impaired action of the organs of digestion.

It is important that, for at least half an hour previous to a meal, and also after a meal, all physical and mental excitement be avoided; the patient should refrain from all bodily and mental exercise, as, labor, running, protracted speaking or singing, serious or active study or thought, sexual cohabitation, etc.; even walking should be avoided as much as possible at such times. The patient should compose his system, and thus prepare his stomach for the meal, and which state of quiet should continue for at least half an hour after finishing the meal. This course will cause the stomach to digest the food properly, prevent disease, impart strength and

nourishment, and entirely obviate dyspeptic constipation. Great care must be taken not to eat during, or immediately after any great excitement or depression of the mind, particularly, *anger, grief, great fear*, etc.; such passions should also be avoided as much as possible after a meal; many a person disposed to apoplexy, or other forms of disease, has brought on a fatal attack by eating immediately after some intense excitement of the mind, and even by becoming angry after a very temperate meal. Cheerfulness and mirth, however, are always proper at a meal, and a patient may feel as happy as he pleases, and also laugh considerably both during his meal and for a short time subsequently. Pleasant tales, agreeable conversation, anecdotes, etc., are always proper at the meal-table, from which everything of a sad, gloomy, melancholy, unpleasant nature should be prohibited. This kind of conversation also prevents us from eating too rapidly, and thereby from overloading the stomach.

Food must always be well and finely masticated before it is swallowed—the finer the better; and the act of chewing or masticating, instead of being rapid, as is too much the case, should be performed with care and moderation, *taking ample time* to perfect its mastication, thereby inviting a flow of saliva to the mouth, which, by mixing with the food, assists the digestive process in effectually digesting it, and also prevents us from putting into the stomach more food than is really required for health. Three meals a day ought to be taken, at from four and a-half to five hours apart, say at seven or eight A. M., at twelve or one P. M., and at five or six P. M. The breakfast should generally be moderate, the dinner sufficiently hearty, and the supper light; and no food whatever must be eaten between meals, neither should any be taken for at least three hours before bedtime. When there is no appetite, do not eat: it is much better to pass one, two, or even twelve meals, than to injure the stomach, and consequently the whole system, by forcing food into it when it is neither craved nor relished. However, when the want of appetite is a condition that will prove injurious to the patient, by adding to the debility already present, a small amount of food in a solid or fluid form, may be administered at suitable intervals, every one or two hours, with three or four stimulating and nutritious injections daily.—There may also be some exceptions to the rule above, relating to food between meals, which must be determined by the physician, who may, in these exceptional cases, allow the patient soups or other light articles of diet at proper intervals between the regular meals.

Below I give a list of proper and improper food for patients

with chronic diseases; the improper food they must on no account use, except by permission of their physician, who must carefully consider the nature of the article about to be allowed, as well as its effects upon each individual. The food given as proper must, nevertheless, be employed with judgment, avoiding all in the list which causes headache, confusion of intellect, nervous derangements, acid stomach, flatulency and disagreeable eructations, weight or heaviness at the stomach, excites internal heat, gives rise to constipation, increases the symptoms of disease, or which disagrees in any manner whatever. Patients ought not to habituate themselves to a low diet, nor to an insufficient amount of food; though such a course may occasionally become necessary, but, fortunately, in very rare and extreme cases. They should eat heartily of every article of food which agrees with them, until they begin to feel satisfied, when they should cease, and in all instances, being especially careful to chew their food well and slowly before swallowing it.

This last measure, as well as regularity in the periods for eating, is an important consideration in the treatment of chronic diseases. Order in meals, both as to time and quantity, is the foundation of dietetic regimen; be careful not to change it. Disease is not only a result of debility, but tends to augment it, and strength and nourishment are to be derived only from the food we take.

List of Food proper for Chronic Patients.

Calf's Head.	Snipe.	*Buckwheat.	Potatoes.
Calf's-foot Jelly.	Teal.	Carrots.	Pumpkin.
*Lamb.	Thrush.	*Chocolate.	Pumpkin Pies.
Marrow.	Wild Duck.	Cocoa.	*Raspberries.
Mutton.	Wild Turkey.	Cooked Cabbage,	Rice Pudding.
Tender Beef.	Woodcock.	without Vinegar.	Sago.
Tender Corned Beef.	Eggs.	Cooked Onions.	Salt, in small quan-
Tender Ham, not old.	Fresh Fish.	Corn Bread.	tity.
Tender smoked Beef.	Frogs.	Dates.	Spinage.
Tender Tongue.	Oysters—roasted or	Figs.	*Spruce Beer.
*Vcal.	stewed.	Ginger, small quan-	*Strawberries.
Venison, tender.	*Turtle.	tity.	Toast Bread.
Hare.	*Crabs.	Hasty Pudding and	*Tomatoes.
Rabbit.	*Lobsters,	Molasses.	*Turnips.
Squirrel.	Shrimp.	*Honey.	Unbolted Wheat
Chickens.	*Muscles.	Indian Pudding.	Bread.
Chicken Pie.	Snails.	*Lettuce.	*Watermelons.
Ortolan.	Asparagus.	*Mead.	Wheat Bread.
Partridge.	Barley.	*Muskmelons.	*Whortleberries.
Pheasant.	Baked Apples.	Parsley.	And as little Spices
Pigeon.	Beans.	Parsnips.	and <i>fresh</i> Butter
Prairie Hen.	*Blackberries.	*Peaches.	as can be conven-
Quail.	Boiled Rice.	Peas.	iently used.

Whatever disagrees must not be used. Although the articles marked with an asterisk (*) sometimes agree with patients, they should be used with care.

List of Food improper in Chronic Diseases.

Any Fat.	*Sardines.	Dumplings.	Radishes.
Fat part of Meats.	Pickled Tunny.	Garlics.	Raisins.
Fat Pork.	Buttermilk.	*Grapes.	Raw Leeks.
Sausages.	*Cream.	Horseradish.	Raw Onions.
Tough Meats.	*Milk.	Lemonade.	Sage.
Tough Salt Meats.	Soured Milk.	Mushrooms.	Shallot.
Tough Smok'd Meats.	*Cheese.	Mustard.	Sour-kroot.
Tripe.	*Apples.	Nasturtium.	Summer Savory.
*Soups.	Capers.	*Oranges.	Tarts.
*Broths.	Cider.	Pears.	Thyme.
Goose.	Cloves.	Pepper.	Truffles.
Duck.	Cranberries.	Pickles.	Vanilla.
Clams.	Cucumbers.	Preserves.	Vinegar.
Salt Fish.	*Custards.	*Prunes.	Water Cresses.
Smoked Fish.			

Nuts of all kinds; all green and hard fruits, also all fruits not named above, whether cooked or not. All high-seasoned food or dressing; cold or warm uncooked cabbage; all excesses in tea, coffee, and gravies; hot bread, cakes, fritters, etc.; and all kinds of fermented, vinous, or spirituous liquors must be avoided, except when the circumstances or condition of the patient will justify the practitioner in allowing them. The articles marked with an asterisk (*) occasionally agree with patients, in which case they may be permitted.

Of all animal meats, *beef* is the most fitted to our stomach, to the maintenance of our health, to the development of our strength. It is a very juicy meat, assimilates thoroughly with our system, and we can always eat of it without having a dislike for it. No other meat, however savory it may be, can, like beef, be used as a daily article of diet without causing a disrelish for it, and a disturbance in the digestive functions. The fat part of the meat should be avoided by patients, who should use the most juicy and tender of the lean parts. Boiled or roasted beef is the best; tender beefsteaks are also digestible and nutritious. When dried or smoked, the tender and juicy parts only should be eaten, and the meat must not be too old.

Mutton, boiled, comes next to beef, being fully as digestible and nourishing, but more apt to cause a disrelish by constant use.

Veal and *lamb* should only be eaten by those whose digestive organs are in a healthy condition, and in the form of a roast; the

flesh of these animals is too young, and has not acquired the maturity and the degree of animalization necessary to our alimentation.

Pork does not readily digest, and is not fit for any one to eat. *Ham*, recent and tender, when boiled, may be occasionally eaten with benefit. The great trouble with pork is that the animals are always more or less diseased, and diseased meat of any kind should never be eaten.

Salted and *smoked meats* are more difficult of digestion and less nutritious than when fresh; they should be avoided by patients, unless their digestive organs are in excellent condition. They should be thoroughly boiled before partaking of them.

The *game* or wild animals named above, also present savory, nourishing, easily digestible, and healthy articles of meat.

Barn-yard fowls, not too young nor too fat, may be eaten with benefit, with the exception of the goose and duck. *Game*, or birds living free, are healthier than domesticated birds. Fowls which are fattened in cages should not be eaten by the sick, as their meat is apt to be diseased.

Fishes, especially salt-water fishes, furnish a very excellent food; those whose flesh is compact, unctuous, and abounding in oil, are of difficult digestion; the patient should prefer those whose flesh can be easily separated, as the carp, salmon, shad, cod, bass, porgy, pike, trout, perch, plaice, flounder, mackerel, herring, whiting, turbot, sole, smelt, mullet, etc. They should be boiled, and eaten without butter, jellies, acid fruits, or high seasoning. *Salted* and *smoked fish* are of difficult digestion, and should not be eaten by patients under any circumstances whatever.

Turtle, cooked plainly, is nutritious and digestible; so are *oysters*, either raw or but slightly cooked. *Crabs*, *lobsters*, and *muscles*, being less digestible, will frequently be found to disagree, and even to produce various unpleasant symptoms. Grated old English cheese, freely eaten, will, it is said, remove the bad effects arising from the use of crabs and lobsters. The meat in the claws is the only part which should be partaken of by patients with whom it agrees. *Frogs* are a very delicate, nutritious and digestible meat, very much resembling tender chicken.

Broths or *soups* are sometimes used when the condition of the stomach will not permit any more solid food; they should be prepared as plainly as possible, avoiding all high seasoning. Unless they are absolutely required, it is always better to do without them.

Soft-boiled eggs agree with most persons; they are tolerably easy

of digestion, and quite nourishing. Eggs are injurious when boiled hard and eaten; so are fried eggs, as well as all fried cakes, pies, omelettes, etc., of which they form one of the component parts.

The moderate use of *pure table salt* upon fresh meats and vegetables, or dissolved in the drinks, is very essential for the preservation of health and continuance of life; salt imparts soda to the bile, hydrochloric acid to the gastric juice, thereby giving health and power to the digestive organs, and it also modifies the elementary or chemical composition of the impoverished blood globules; it is, therefore, of especial value among those who are lymphatic, or are laboring under phthisis, scrofula, tubercula, etc.,—among such, bread and fresh meats with salt, as well as oysters, eggs, and other articles containing similar principles are always indicated.

Vegetables are eaten along with animal substances to vary our food, satisfy our appetites and tastes, and to balance the too nutritive action of the animal diet. *Wheat*, formed into bread, is a very common and well-known nourishing article of diet, and is more restorative and more easy of digestion than either rye or barley. *Rice* may be said to stand next to wheat as an article of diet; then *oats*, *Indian corn*, *potato*, *vermicelli*, *maccaroni*, etc.; but articles which are apt to be adulterated we must be very careful about, as sago, arrowroot, tapioca, etc. Boiled *beans*, *green peas*, and soups of these legumes are frequently of benefit. *Artichoke*, *salsify*, *cauliflower*, *pumpkin*, *turnip*, *beet*, *carrot*, *asparagus*, *spinage*, *sorrel*, *chicory*, *lettuce*, etc., frequently agree with patients; but they should be used with salt, and without oil or vinegar, and be eaten with meats or fish. All strong, aromatic, spicy or stimulating vegetables should be avoided as much as possible; most generally they will be found to disagree. *Melons* and *watermelons* are hurtful to those laboring under affections of the digestive organs; when permitted, they should be partaken of sparingly. *Strawberries*, *raspberries*, *blackberries*, and *whortleberries* are particularly refreshing when they agree; the first and last will be found beneficial in certain affections of the kidneys and bladder. All ripe fruits may be allowed when they do not interfere with the action of medicines, nor cause any disagreeable symptoms. They may be used either crude or cooked, as best agrees with the patient, and prove valuable by keeping the bowels regular, as well as by the acid and potash they impart to the system. Many dried fruits effect the same object, as figs, prunes, etc.

It must be recollected that there are many articles of food

which, although harmless to the healthy person, are extremely deleterious to those laboring under disease. The physician should be thoroughly versed upon these matters, in order that he may understand how to prescribe for his patients with judgment and accuracy. A more extensive reference to them, and to other points connected with Hygiene, will be found in the Introductory Remarks of my popular work, the *American Physician*, together with a statement of the several constituent principles entering into the composition of the various substances used as articles of diet. *Pereira on Diet* will likewise be found a highly useful work for the practitioner.

The profession of a man is always a constitutive part of his hygienic condition. The professions engender habits and place man under conditions which make part of his existence. Each profession should follow a particular regimen; a solid, nutritious diet to the hard-working man; a light and less substantial one to those of sedentary habits. Also a greater quantity of nourishing diet to young folks than to persons of middle age, and especially to old folks, as digestion is more active while the body is increasing in growth.—If laboring men knew how much more preferable were their appetites provoked by labor, the tonicity of their stomachs, the functions of which nothing can derange, and the happy habit of frugality they have acquired,—to the impaired and vitiated tastes of the rich and voluptuous, they would never desire to sit at their tables. These persons, who are supposed to be so happy, envy laboring men their appetites and their healthy digestive faculties. It is not among millionaires and men of the world that we find persons who have lived a hundred years; it is among sober, laborious, and continent men. Whoever seeks the pleasures of the table and of sensualities finds only satiety and disease. The less we season our food, the more healthy will it be; the less we seek to vary it, that is, by the addition of spices, high-seasonings, modes of cooking, etc., the less we will eat, the less we will impose upon the stomach, and the better will the food be digested; and a good digestion of proper food gives healthy chyle; the healthy chyle makes pure blood, from which results good health; weaknesses, losses of appetite, headaches, bad dreams, and indigestions, all now disappear, and a better order of things ensues. Bread, milk, some leguminous plants, with fruits, and pure water, and an occasional addition of fish or meat to the meal, say once in every week or two, will be found fully sufficient for plethoric persons, and those disposed to congestions and inflammations. How many robust men have employed only this diet, and thereby pro-

longed their lives! With those who have a more active stomach, but a weak body from a defect of assimilation, a more animalized diet will be required. With others again, a combination of meats and vegetables, temperately employed, say during one or two meals each day, will be required, especially among active laboring men. Mankind eat too much; dinner kills one-half the inhabitants of large cities, and the supper destroys the rest. We see these portly citizens, these slaves of good cheer and wine, these florid and full faces, and we think they have the appearance of health. But they are likewise indicative of the approach of disease; of gout, of derangements in the digestive organs, or of the respiratory organs, of commencing congestions, of menacing apoplexy, the inevitable punishment of intemperance. How many opulent men, given to good cheer, have taken a nap after a hearty meal from which they have never awakened! If imprudence in diet affects healthy persons in this manner, how highly important is it that the diseased should adopt a more natural and temperate method! Food and drink of bad quality, as well as intemperance in eating and drinking, are most fruitful sources of disease and death. Our food should be plain and simple, but varied, not living exclusively on one article, for both the stomach and the system are better satisfied with variety than with sameness.

Every time that the stomach experiences a sensation of fullness, that the mouth is clammy, that the bile flows sluggishly, that the head aches or becomes dizzy, that palpitation of the heart is present, or that hypochondria attacks suddenly, remember that the more the stomach is kept empty, or is only partially filled, the less subject to disease will be the person.

In cases of children, and adults with delicate stomachs, and in instances where the treatment will require many months, or even years, to effect a cure of disease, medicines may be combined with the daily food with very happy results. Thus, many of the preparations of iron, cimicifugin, leptandrin, podophyllin, etc., may be mixed with the bread and cakes; while chocolate may be sweetened with one of the various alterative syrups instead of sugar, and may even have certain tinctures or infusions added to it; being careful in all these instances that the articles added are compatible with the elements of the food, and the conditions of heat, cold, etc., which may be present, in order that decomposition may not ensue, or new and undesirable compounds be formed,—the quantity of medicines added to the food for this purpose should never be so great as to materially affect its taste. By such a course as

this, I have obtained most wonderful and unexpected salutary results in a great many diseases,—the patients not being aware that they were taking any medicine.

DRINKS.

The best, the most salutary fluid presented to us by nature for quenching thirst and supplying the demands of the system for more fluid, is *water*; it is found everywhere, costs little, and is of infinite value. It is the sole drink of non-civilized nations, and the examples of strength and vigor among these nations, as well as the generally prolonged life, free from disease, of abstemious persons, ought, it seems to me, to open the eyes of those who believe tea, coffee, wine, etc., indispensable to life. To civilization alone is due the multiplicity of infusions, fermented, and alcoholic fluids, invented to afford momentary relief to a languid organism, and to satisfy our desires for excitement and sensuality. Tea and coffee are useful, relatively. As to their moral effects, either of these drinks may be substituted for vinous liquids without exciting the same inconveniences upon the organs. Many people use tea and coffee to favor the digestive functions; tea excites in an especial manner, and its effects are experienced for several hours after the meal. The stimulating property of coffee is well known, and its aromatic infusion taken in moderation, a short time after a meal, develops the activity of the digestive system, and gives an increased energy to the mind, which favors all its operations. Nevertheless, pure fresh water is suited to all ages and all constitutions; it aids digestion, improves the appetite, and is conducive to health and longevity. Sweetened dishes and sugared water should be avoided as much as possible in most chronic affections.

Distillation appears to be the most unlucky present that chemistry has given to the human family. *Stimulating drinks*, instead of appeasing thirst, increase it; instead of augmenting strength, they exhaust it; even their moderate use causes irritation and weakness, while their excess degrades and consumes reason. More persons die prematurely from alcoholic drinks than from all diseases combined. How many young and robust men are carried off by even their moderate use—while, on the contrary, how many men owe to the use of water a lusty and healthy old age! Michael Kiavelkis, of the government of Vilna, never drank anything but water, had been married to several wives, and at the advanced age of one hundred and thirty-seven years left thirty-two children, several of whom, having followed a similar regimen, have attained nearly or quite a hundred years. M. de la Quersonier, of Paris,

led a life of temperance, drinking nothing but water, for sixty years, and reached the extreme age of one hundred and forty years.

Persons not in health, and old men, may, however, make moderate use of *wine*, mixed with water, as a mild stimulating tonic; it may also be used by patients who have been accustomed to the use of brandy and stronger drinks. It is also proper, as a medicine, for lymphatic persons, and those laboring under scrofula, phthisis, tuberculous affections, etc., with whom the moderate use of even stronger drinks often proves advantageous. As a general rule, all wines and liquors should be prohibited among patients of sanguine, bilious, and nervous temperaments. *Beer*, *ale*, and *porter* are of occasional service among persons much debilitated by Chronic disease; but the danger is that when once allowed as a medicine, patients will use them beyond the bounds of moderation. *Toast-water*, *rice-water*, *barley-water*, slightly sweetened and flavored with a little sherry wine, or with the juice of those ripe fruits known to agree, will generally be found much superior as a stimulant and tonic to any of the ordinary malt liquors. Malt liquors are especially injurious in most diseases of the kidneys, bladder, and urinary organs, also in all chronic diseases of the mucous tissues. *Spruce beer* and *mead* may be temperately used by patients when they do not disagree; however, they are of no practical advantage in a therapeutical point of view.

There is one thing which must especially be noticed in the treatment of chronic disease, which is, that, where patients have been habituated to the daily use of vinous, alcoholic, or other liquors, they must never be abruptly deprived of them, but be allowed a reasonable quantity during treatment. The sudden withdrawal of such drinks from patients accustomed to their use, will, according to the character of the disease, either aggravate it, or give rise to serious symptoms. Too much care can not be had in this respect.

Cider, *perry*, *lemonade*, *sour wines*, and other sour drinks, however palatable and refreshing they may prove at the time of taking them, are apt, from their own acidity, or from the acidity they develop in the stomach, to neutralize the action of medicines, and are consequently improper drinks in chronic disease, especially where there is a tendency to acid stomach and flatulency. If permitted to be used at all, it must only be after a careful investigation, by the physician, of all the circumstances and conditions of the patient, and of the effects of such agents during a reconnoitring trial of them. *Soda-water*, *mineral water*, *syrupy drinks*, *infusions*,

decoctions, and other drinks not referred to in this place, are subject to this same general rule.

Tea and *coffee* are active stimulants, and although of extensive use by both sick and well, the habitual daily employment of them is highly pernicious, especially when used in excess and of great strength. Although patients will do better without them, yet there may be instances in which the physician may safely allow them to be used at meals, in moderation and quite weak. Persons who are endeavoring to break off the use of alcoholic drinks may certainly be permitted the use of tea and coffee. Tea and coffee lessen the amount of matters excreted from the tissues in their process of decomposition, as manifested by the diminution of the amount of urine and feces passed, and, therefore, may prove beneficial by retarding the too rapid disintegration of the albuminous tissues of the system. Infusions of many of our simple or bitter herbs will often answer a much better purpose than either tea or coffee, as mild stimulants, when compatible with the medicines prescribed for the patients. *Chocolate* may be used wherever it agrees with patients, but a weak infusion of *cocoa* is preferable.

As a general rule, then, water is the best beverage for patients laboring under chronic disease. "Drink water," said the celebrated Dubois to the young persons who consulted him, "*Drink water, I tell you.*" Dumoulin, the medical Dubois of his time, wrote, previous to his death, "*I leave two great physicians behind me,—diet and water.*" But other drinks, of a refrigerating, tonic, or stimulating character, may be employed in certain cases, and always more with a view to their beneficial therapeutical effects, than to any desire or necessity for them as beverages. Drinks which determine to the skin, and do not disagree in other respects, by producing gentle perspiration often prevent disease, which is very frequently the result of suppressed perspiration.

Patients who have been accustomed to the daily use of liquors, are very apt to fail if their usual stimulus is too suddenly removed from them; in such cases the physician will find it beneficial to allow a certain amount of liquor to his patients daily, the quantity and quality of which he should carefully prescribe or permit, according to the circumstances attending each invalid, being careful not to allow enough to overexcite the circulation.

TOBACCO.

An energetic poison, tobacco has, nevertheless, become one of the most imperious wants of our enfeebled and obtuse epoch. We

snuff, we smoke, and we even chew this acrid and corrosive substance, which weakens the brain and nervous system, and which injures the powers of digestion by destroying the tone of the stomach and biliary organs. Like the Orientals, who stupidly seek, in opium and haschisch, for visions and hallucinations, we foolishly expect to revive our spirits and to forget our miseries under the effects of liquor and tobacco; and even those who strenuously discountenance the use of liquor are perfectly intemperate with tobacco. An oppressive torpor, weakness or loss of intellect, softening of the brain, paralysis, nervous debility, dyspepsia, diseases of the liver and kidneys, and gravel, are affections which are by no means uncommon consequences of an excessive employment of this weed, the poisonous element of which is the nicotine contained in it. Independently of these maladies, it is a filthy practice to use it at all, as manifested by the uncleanly noses, the foul handkerchiefs, the soiled clothing, the filthy and spotted floors and walls of the bedroom, sitting room, and other places, where tobacco consumers expectorate, the discolored teeth, and the detestably fetid breath. And there is hardly to be found a person engaged either in chewing, smoking, or snuffing tobacco, who does not frequently experience warnings against its use, in the form of faintness, nausea, giddiness, extreme dryness of the throat and fauces, nervous tremblings, and more or less sickening debility, with prostration of the vital powers, and feelings of fear, disquietude, and apprehensiveness. Many of which effects, it is proper to remark, may be overcome by large draughts of cold water.

It is a remarkable fact, which all physicians of much experience will corroborate, that, in the treatment of chronic diseases, those who are addicted to the use of tobacco in any form, are, as a general rule, found to be much more difficult of cure than those who do not use it; their nervous systems respond more feebly and slowly to the action of remedial agents, and which is due to the tobacco which has blunted and paralyzed the extreme susceptibility of their nerves to both external and internal influences. A patient under treatment should give up the use of tobacco, or else his physician should assume no positive responsibility in his case, further than to do the best he can for him; by stopping its employment the patient will be astonished at the rapidity of his cure and at the more active salutary influences of remedial agents upon his system. In some cases the suspension of its use may be effected at once; in others, it will require to be gradual; thus snuffers and smokers may stop at once; but old chewers should

gradually lessen their *cuds*, and at the same time acquire the habit of chewing chamomile flowers, boneset leaves, or the inner bark of wild hickory—the latter being the best tonic to restore the tone of the stomach, without interfering with any other therapeutical treatment that may be instituted.

AIR.

Air is still more indispensable to health and life than food; we eat only two or three times a day, but we respire incessantly day and night. The air sustains life by its double action upon the lungs and upon the skin. In the act of respiration, hematosiis or sanguification is produced, by which the black blood is transformed into red; if the air be pure, the blood absorbs a full amount of oxygen, is revived and perfected; if the air be impure, the blood is impoverished according to the deficiency of oxygen and the character of the impurities. In its action upon the skin, the air maintains perspiration, and favors the elimination of the superfluous elements which must be rejected from the economy. This last function is the complement of the first. The one can only be effected by the incessant introduction of air into the lungs; the other is only perfectly executed when the waves of air, upon coming in contact with the skin, successively removes the fluid which it exhales.

The action of the air is, then, an indispensable condition to the maintenance of these two conditions. But although the lungs possess a ventilating apparatus, and although the action of inspiration and expiration is sufficient to introduce air into the extreme bronchial ramifications, ventilation of the skin can only be carried on by the impulsion which the air receives on the outside. Hence, when men or animals are inclosed in dwellings, they are deprived of this cause of impulsion, the skin then becomes inactive, and perspiration is diminished unless muscular exercise is called into play to re-establish the equilibrium.

By a kind of intuition common to every body, many physicians, both among the ancients and moderns, have foreseen and pointed out the twofold and beneficial influence of muscular action and of the atmosphere in motion; but they have not fully comprehended all its value; they have not laid down principles nor deduced consequences. Nevertheless, a host of observers, under the relation of hygiene, have made known in an empirical manner the necessity for exposing man to the open air, and the danger of a sedentary life. Children should be allowed plenty of air, and, even in winter, should be accustomed to expose themselves bareheaded to

the wind and to the sun. True, this will darken the skin of girls, but it will preserve their health and strength; they will become less susceptible to atmospheric impressions, and will have less to fear from scrofula, consumption, tuberculous, rheumatic, and other diseases. When they reach that period of their existence in which, according to the custom of society, they ought to enjoy the precious advantages of youth and beauty, the remaining in their dwellings will soon impart delicacy and brilliancy to their complexion; they will then reap, even to their last days, the fruits of the salutary liberty and of the energetic education of their childhood.

From the cradle, in the first year of existence, we must gradually accustom infants, with much discretion and prudence, to the influence of external agents; their linen ought to be frequently renewed; light clothing, porous and of sufficient warmth, should preserve the fragile creatures from cold and moisture; but, if we do not desire to render them susceptible to the least cold, to the slightest changes of air, and dispose them to croup, to looseness, to cutaneous affections, in fact, to a host of diseases, we must not soften and weaken their skin by exposing them to a too elevated temperature, nor excite a profuse moisture by means of thick coverings. Not only is it necessary and useful to carefully expose them, according to their strength, to the light and open air, but, whenever the heat of their apartments will permit, it will prove a good plan to remove all their clothing, and allow them to kick and move about, at will, in their original nudity. As soon as their strength and age will permit, they should be frequently taken, in seasonable weather, upon high hills, near woods, and in meadows, and be there allowed to carry on their sports, their racings and rompings, and their games.

As the years roll on, the habits change; and in our desire to make scholars, we forget to make men. But with more care and wisdom in our methods of education, we may easily reconcile the all-powerful advantage of health with the precious development of the intellect. For instance, what is there to hinder teachers and professors from giving to their students, during promenades in the country in fine weather, the principal ideas of which they ought to be masters? In climates of mild temperature, why can not these lessons be carried on under tents, or at least in places accessible to the sun and open air? Why do we not apply ourselves to the purification of the air, and of keeping it in motion, in our dwellings, our schools, our colleges, our churches, etc., by means of a natural or artificial ventilator, which may be substituted for

the action of atmospheric currents upon the skin? Indeed, such apparatus should exist in all establishments, of whatever character, where air becomes vitiated by the gathering of a number of persons, where deleterious miasmas are evolved, and where, either from poverty or legal punishment, man is doomed to inaction and dampness. In hospitals and other establishments in which ventilation is obtained, the functions of the skin are carried on more healthily; convalescents more rapidly recover strength; wounds assume a better aspect and heal more rapidly; lying-in women are less exposed to dangerous consequences; and scrofula, consumption, and other chronic diseases are more rarely met with.

We should seek, then, to secure for patients, as well as for those in health, a pure and perfectly oxygenized atmosphere; aerate their dwellings, and do not stop the chinks of doors and windows with wads or listing; in the warm nights of summer have their windows open, unless they live in objectionable locations, and, even then, the free night air, as impure as it may be, will be preferable to the confined and more highly contaminated air of the bedroom; and, whenever the weather and temperature will permit, advise them to sleep in places, and under conditions, where they may constantly breathe a fresh supply of air. Guard them, however, as much as possible, from foul and pestilential air, as well as from dampness.—Patients residing in unhealthy districts should never be allowed to go out to exercise in the early morning air until the atmosphere has been purified and vitalized by the sun's rays, and they should retire within doors about an hour before sunset.

They should shun all crowds or assemblies where the atmosphere is vitiated, and rendered unfit for respiration, by the dust, the combustion of lamps, and the poisonous emanations from the skin in perspiring, and from the lungs in breathing. They should keep no flowers nor perfumes in their sleeping apartments, for strong odors asphyxiate. Give air to their bedrooms, and do not encumber them with lodgers. Even in summer, sleep in rooms with chimneys or ventilators, by means of which the air may circulate with greater force and freedom. Prefer a southern apartment, with high ceilings, and avoid as much as possible a northern aspect and dampness. Where the sun does not penetrate, the physician enters. An abundant source of heat and life, the sun is eminently the plastic power; it repairs, it reconstitutes the enfeebled being; it arrests disease; it favors remedial treatment; it produces wonderful cures. If possible, inhabit, as a matter of preference, the neighborhood of gardens and trees; for plants, by

absorbing deleterious gases, are the most useful purifiers which the kindness of nature has given to man.

As a general rule, a country residence, with daily exercise, and an abundant and healthy diet, is more conducive to health and long life than any other; but we should be careful to avoid low and moist lodgings, among putrid manure, or near ponds of stagnant water, or collections of decomposing vegetable matter. How many unhealthily located villages are there, situated in the neighborhood of marshes which exhale death, or in the midst of forests of high trees which prevent a free circulation of air! How many communities are there who have for a constant drink only a salty, brackish, soapy, limestone, or other impure water!

Although mortality is not so great among those laborers who can supply their wants by constant employment, it is frightful among artisans who are out of work, and among their families. One-fifteenth of these persons die annually, and two-thirds of their children never reach the age of two years. Inhabiting low and damp houses, illy ventilated, deprived of sufficient light, situated in narrow and filthy streets in the center of large cities, burdened with cares and fatigues, badly nourished, undergoing all the inconveniences of uncleanness, and often abusing spirituous liquors to drown all thoughts of their grievous condition, they not only occasion disease among themselves, but also give existence to numerous sickly children, who are suckled by unhealthy nurses, and are abandoned to themselves as soon as possible.

Pure air gives health to the lungs, richness to the blood, full development to the organs, and health and strength to the system; a vitiated air diseases the lungs, impoverishes the blood, debilitates the organs, and causes debility, sickness, and premature death. Sea air is generally purer and sharper than inland atmosphere, and is especially serviceable to scrofulous and lymphatic patients, and to those whose diseases are due to the influence of unhealthy vapors.

CLOTHING.

Clothing is not only an object of luxury, of coquetry, of fashion, of social distinction, and required to conceal nakedness, but is an object of the highest necessity in a hygienic point of view. In this respect it guards the body against the influence of atmospheric changes, maintains it at a proper temperature, and preserves the skin from injurious contact with external objects, as insects which prey upon the blood, poisonous vegetables, etc. General rules only can be given relative to clothing. Cleanliness

of person and of dress are important items in the treatment of disease; slovenliness is to the body what vice is to the mind,—in this relation, there is an astonishing connection between the physical and the mental.

No more clothing should be worn than is necessary to keep the body comfortably warm, being careful to regulate the amount according to the increase or decrease of temperature. Too much clothing injures the functions of the skin, on account of the excessive heat and perspiration it occasions, and which will ultimately give rise to disease of some of the internal organs. While too little clothing exposes the system to the influences of cold and sudden changes of temperature, likewise terminating in disease. Patients should be more particular in this respect than healthy persons. It is not the cold which we must fear, but a sudden or unexpected cooling of the skin, or suppression of perspiration. Complicated inflammations of the organs of the chest, as, pneumonia, pleurisy, fatal arteritis, have frequently resulted after a ball, from the skin, covered with perspiration, becoming suddenly exposed to a cold air. Sometimes, phthisis is revealed; but when this is the case, we may rest assured that tubercles previously existed in the lungs. In healthy villages, or localities exempt from dampness, dancing does not produce similar results among the country parties who, after having amused themselves with this agreeable exercise, frequently take long nocturnal promenades in the fields and woods without experiencing any bad results.

The thickness and character of the clothing should vary according to age, climate, and season. When the atmospheric heat is considerable and uniform, cotton and linen should be worn, being careful to have the clothes of sufficient amplitude to permit a free circulation of air through them. But in countries where the changes of temperature are frequent, where cold and moist winds suddenly succeed to an oppressive heat, it is indispensable to wear woolen clothing, which, being bad conductors of heat, present a barrier between our own heat and that from without. In these cases, the clothes should fit more tightly than in the previous instance, to prevent the free passage of a cold or damp air. The Romans and Spaniards most generally wore a mantle when they feared these atmospheric disturbances. The Russians, and especially the inhabitants of St. Petersburg, during the days of their burning and fugitive summers, never go out without carrying with them their paletot or their *bekech*; and strangers, used to other climates, who omit this precaution, believing they can safely dispense with it, often fall victims to their imprudence. A diarrhea,

a dysentery, an intermittent fever, etc., convinces them, when too late, of their error. We may despise the counsels of one man, but we must never disregard that which an entire nation has adopted; then, take the mantle in Spain, and the paletot in Russia, for the proverb is true that says "draughts of air kill more than cannon balls."

Persons laboring under chronic rheumatic affections, neuralgia, chronic catarrh, or who are disposed to tubercles, and also delicate children who are readily susceptible to the influence of cold and dampness, ought to wear flannel next the skin. But in the age of vigor, and in salubrious climates, it is a dernier resource; we must then only employ it when all other means which may strengthen the skin and render it less susceptible, have been unsuccessfully tried. Flannel should also be worn where hot days are succeeded by cool nights, and in damp and changeable climates.

Clothing should never be so tight as to compress or interfere with the motions of any part of the body. The cravat, the collar, stocks, gaiters, and bands, should be as loose as possible. Tight corsets, though they may not produce tubercles, will undoubtedly favor their formation. Yet sometimes they may be serviceable among persons disposed to assume vicious attitudes; but such ought to prefer the small corset to the large one, which protects and supports the breasts without causing them to become smaller, and which maintains the trunk in its natural straightness, without interfering with the free action of the lungs and heart. Undue compression upon any part interferes with the functions of that part, and disease is certain to be the result, sooner or later.

Head-dresses, hats, etc., should be sufficiently large, light, and with deep rims or borders in summer, in order to protect the eyes from the rays of the sun, being careful, however, to allow the head to experience the influence of atmospheric contact as much as possible, either by orifices in the hat, or by keeping the head uncovered whenever the circumstances will permit. Be sure to keep the head cool.—Shoes should be pliable and elastic, light and thin in warm weather, thick and warm in winter, and thick and impermeable in damp weather. The feet should be kept warm and as dry as possible; and patients should wear woolen socks or stockings during cold and damp seasons; especially those whose feet perspire freely.

EXERCISE.

Exercise, regularly and properly taken, is one of the most efficient resources against the formation of chronic diseases; it neu-

tralizes the sad effect of intellectual excitements, and strengthens the resisting power of man to the action of injurious external causes; it impresses a salutary movement upon the circulation from within outward; it augments the animal heat, and develops and strengthens the muscles and organs; it imparts to the body greater suppleness, agility, force, and elegance, and to life more energy, tenacity, and duration.

On the contrary, inaction, idleness, excessive rest, diminish vital heat, enfeeble organic movements, paralyze the brain, heart, muscles, and the whole organism, causing them to fall into a painful inertia, a dangerous debility.

Exercise increases power, perfects the faculties, forms, and health; idleness and inaction debilitates, and brings affliction and degeneration. With the first, respiration is rendered easy, the cheeks become more ruddy, the body more agile, the mind more vigorous and joyful; with the latter, follow paleness, bloating, oppression, lowness of spirits, melancholy, and a fatal disorganization. Persons who exercise, who are constantly exposed to the influence of light, and of the open air, are much less subject to chlorosis and anemic conditions, to nervous overexcitations, to organic derangements, scrofula, consumption, etc., than those who dwell in cities, exercise but little, and are mostly within doors. Physical development is much more indispensable to health and life than intellectual, because health is the first of all blessings, and life the most precious of all gifts.

Living in large cities, as well as spectacles of vices and passions, sadden the mind. A country life and a taste for gardens contribute much to prolong our existence. A pure air, simple and frugal nourishment, exercise of the body, order in all its actions, and an attention to the works of nature, give to the mind tranquillity, serenity, and gayety. Man was not created to meditate unceasingly, but to work and act. Idleness fatigues him, or drives him into vices; inaction sickens him. Between the brain and the stomach there is an intimate sympathy; if the head becomes too strongly occupied, digestion becomes laborious and painful; how many are there who can not devote themselves to even the most superficial study after their meals? Woe, then, to those who wish to exist only by thinking, who sacrifice everything to labors of the mind,—they run after glory, and wear out their bodies, lose their healths, and extinguish their mental powers, without attaining it. Music, songs, spectacles, cheerful society, plays, and the pleasures of consolation, rest and relieve the brain. When the morning is devoted to mental labor,

give, at least, the rest of the day to agreeable exercise and entertainments.

To be beneficial to patients, exercise should be pursued with regularity and moderation, should be taken as much as possible in the open air, and should always be pursued, not as a task, but as a matter of recreation, surrounding it with all associations calculated to give rise to cheerfulness and pleasing excitement. A patient, when advised to exercise, may reply that "he or she has plenty of it in the daily labor he or she pursues," that "his business gives him plenty of it," or, that "she has plenty of exercise in attending to her domestic duties." But, the physician must recollect that this is not what I mean by exercise, especially in its application to those under medical treatment; these are daily tasks, labors, and often hard labor at that. Exercise is of a different character; it must have no reference to business, labors, nor to household occupations,—but only to health, and for this purpose it must be associated with everything calculated to produce agreeable mental excitement freed from the cares of life,—and unless this be done, but little benefit can be expected from it. The kind of exercise I refer to, will frequently cure apparently obstinate diseases, of long standing, without the aid of a particle of medicine. The nature of the exercise advised to patients must be adapted to their disease, their strength, and their circumstances. With some, riding in vehicles, or on horseback, sailing, cultivation of gardens, etc., will answer; while others will require a more active kind, as running, jumping, lifting, swimming, rowing a boat, etc. Carefully conducting the exercises according to the more recent standard works on Hygiene.

Dancing, with accompanying music, is a very excellent exercise to excite the nervous system, and, by the gayety it inspires, to increase the action of all the organs, to augment the rapidity of the circulation and the frequency of respiration, to cause the blood to determine to the capillary system of the skin, increase the animal heat, and give rise to free perspiration. Dancing, often repeated, gives to the body an easy and agreeable carriage, causing it to move with more grace and freedom; the shoulders become thrown backward; the lower limbs gain in strength and suppleness; their muscular masses assume more energetic and rounded forms; and the circulation in these limbs becomes more active and natural. But, in order that beneficial results may be derived from dancing, it must be stripped of its mischievous concomitants. Thus, this exercise should be carried on in the day-time, in well-ventilated halls in cold weather, and in the open air during warm seasons, and should never be carried to excess. But, when pursued during the hours which

should be devoted to sleep, with all the accompaniments calculated to intoxicate and give energy to the passions, dancing fails to be of hygienic utility, and in its moral influence, often triumphs over the most chaste education and the most salutary precepts. But, an abuse in the application of a principle, is not sufficient to destroy its value.

Frictions upon the surface of the body, together with shampooing, will be found a most efficacious measure in all chronic diseases, and especially among lymphatics, sedentary persons, and those laboring under rheumatism, paralysis, dyspepsia, liver diseases, consumption, numbness of limbs, constipation, prolapsus uteri, etc. Frictions remove all impurities from the skin, determine the blood to the cutaneous capillary vessels, improve nervous and muscular power, impart energy to the brain and nervous system, as well as to the digestive apparatus, and increase the resisting power of the system to morbid influences. Shampooing is a still more powerful passive exercise, producing all the beneficial results of friction, together with a decidedly more powerful salutary effect upon the deeper seated parts. Shampooing must be performed by a second party, while friction may, according to circumstances, be performed either by the patient himself, or by his assistant.

In nearly all situations of life, exercise taken sufficiently to provoke a gentle perspiration, with frictions repeated daily, and continued each time until the skin reddens and has a gentle glow of heat, and the use of clothing which facilitates moderate sweating, will be found to produce the most happy results. How many engorgements and visceral derangements have yielded to continued exercise, to the oft-repeated jolts of horse riding, to active sports, or to feats of strength! Man should frequently change his place. Frederick the Great remarked: "When I consider the physical constitution of man, I am induced to believe that nature made us for the state of postillions, rather than for that of scholars."

Singing and laughing during the exercise are of remarkable efficacy in giving tone and power to the lungs, and through these organs to the whole system. Every patient should daily practice these in a moderate degree, so as not to fatigue the organs nor irritate the vocal apparatus; and if he can neither sing nor laugh, he should at least attempt them, and do as well as he can. Shouting aloud, and hallooing, especially in the open country or sea air, are also of great utility in many cases. Of course, the extent to which these vocal exercises may be carried in conjunction with the corporeal, must be judged of by the physician in each particular case.

Swimming in sea water gives more energy to the constitution,

more pliability to the limbs, and greater firmness to the flesh, and is of immense utility as an auxiliary in the treatment of nearly all chronic diseases. However, in certain organizations, especially feeble ones, prolonged cold bathing will give rise to derangements, and we should carefully limit the duration of, or entirely prohibit, bathing, among those who on entering the water, experience an intense chilling, with paleness of the face and extremities and involuntary trembling. But if, on the contrary, after the first impression, the skin reddens, the strength increases, the respiration becomes more free, and the appetite improves, we may unhesitatingly advise its continuance. A promenade along the borders of a river, in the country, or on elevated places, after the swimming, is always necessary, and will, from the act of walking, the influence of the light, and the inhalation of pure air, powerfully favor a reaction, without which cold baths are apt to be more hurtful than salutary.

Traveling is of great value to those patients whose means in life will permit it, especially with those laboring under scrofula, gastralgia, chronic irritations of the stomach, hypochondria, melancholy, mania, chlorosis, and other anemic conditions. The change of air, scenery, and excitements, the mental and physical activity effected thereby, the forgetfulness, as it were, of one's self, and one's afflictions, produce very beneficial results. For the anemic, all these circumstances may be met with at some popular chalybeate springs.

Sea voyages are of much service. Sailors generally enjoy a robust health, although they pass frequently from warm climates into those of intense cold, and are exposed to all the vicissitudes of the weather. Tuberculous patients and those laboring under the *early stages* of consumption, will derive great benefit from sea voyages; instances of permanent cures therefrom are by no means rare. But, in order to derive the full benefits of travel by sea, patients should as much as possible adapt themselves to the duties and fare of the seaman; a mere journey across the sea, without muscular exercise, and with a diet consisting of delicacies, will be of little avail to the invalid.

Sailing on rivers is likewise beneficial; in rowing a light boat, the muscles of the superior extremities and of the chest, are developed: a pure atmosphere, and in motion, is respired, the undulations of which being incessantly renewed and brought into contact with the skin, excite the depuratory functions of this membrane to a normal action.

Visiting the springs, or employing mineral waters, is undoubtedly of great value to patients with chronic disease. But the difficulty is, that the physician too frequently recommends them when the disease is incurable. When medicine is powerless, the physicians

having employed all their resources, the mineral waters are recommended, and the patient has then no chances of cure. If used at all, it should be in the early stage of disease.

But, however beneficial mineral waters may be, their improper use will only aggravate disease which might be modified by a proper employment of them. The use or application of any spring waters exacts knowledge, judgment, and prudence; not only must the proper kind of water be selected and prescribed, according to the character of the disease, and the constituents of the water, but the physician must also take into account the age, the sex, the temperament, and the degree of the strength of his patient, as well as the more or less advanced stage of the disease, and its complications. It is much better for patients not to make use of mineral spring waters, than to use them unadvisedly, and without system or design. Those physicians residing in the neighborhood of medicinal springs, who have more particularly devoted their attention to the virtues of their springs, are the proper ones for patients to consult with relative to their individual cases, that is, as to the suitableness of the water to their disease, the manner of using it, and the auxiliary measures to be attended to while taking it. The medical attendant of the patient should always counsel with the physician at the springs, as long as his patient remains there, without necessarily yielding up his patient entirely to the latter physician's charge.

Persons afflicted with chronic disease of any kind, must at all times assume a perfectly straight condition of the body, with the shoulders thrown back, the small of the back curved inward, and head erect. This must be attended to whether sitting, standing, walking, writing, reading, sewing, etc., and pressure of the chest or stomach against a desk or counter must be avoided, as well as sitting with the body doubled forward. By not attending to this posture, the stomach is pressed against the diaphragm, the capacity of the chest is consequently contracted, and the passage of the blood through the heart impeded, giving rise to short or difficult breathing, palpitation, disease of heart and lungs, pains in the small of the back, female difficulties, dyspeptic symptoms, and often sudden death, particularly after meals in persons laboring under affections of the heart. Many diseases are either caused, or rendered worse, by the lazy, stooping, bent-over posture, which is unnatural and unhealthy.

SLEEP.

Rest is an imperious necessity for all animated beings, and especially for persons laboring under disease. Rest must not only be had at various intervals during the waking hours of patients

throughout the day, but likewise by a sufficient amount of sleep during the hours allotted for this purpose through the night. During sleep there is a temporary cessation of the functions of the brain and of the nervous system of the life of relation, while, at the same time, the material losses which these organs have experienced in the previous waking state are restored. The duration of this passive condition of the organs should always be proportioned to their state of activity. If the sleep is not sufficiently prolonged, if the rest is not complete, the powers of man are weakened, his body becomes exhausted and lean; the organic molecules which he has lost through the day are not replaced by new ones; his skin becomes wrinkled, the freshness of early life disappears, and, with him as with animals, a premature old age is the inevitable result. Such is the law of nature.

But this law is modified according to climate, sex, and temperament. Very exacting in the inter-tropical regions, the need for sleep is much less than in those of the North, where motion becomes a necessity. Although it may not be possible to assign a precise limit to its duration, we know, however, that this is much more considerable as we approach nearer the period of birth. For the infant who is exposed to an incessant agitation, it is indispensable that it sleeps not only through the night, but also during certain hours of the day. The periodicity of sleep can not be explained by the exhaustion of the nervous influx, for the enfeebled old man sleeps much less than the infant with all its turbulence, or the man with all his vigor. Persons who eat a great deal and who use stimulating drinks, frequently experience an invincible tendency to sleep; this may be removed by a return to habits of temperance, or at least we may diminish the faulty tendency and the danger of cerebral congestions to which it disposes. We see that there are intimate relations existing between the wonderful mechanism of the brain, and those of the stomach which digests and of the muscles which contracts. The same principle animates them; but the two opposite poles of the nervous prolongation, the brain and the generative organs, are subject to the law of intermittence of action; while, by an admirable foresight of nature, the heart and the other organs of vegetative existence, which receive the nervous influx of the central parts of the same prolongation, are not subject to the same law. Their motion commences and ceases with life.

The normal duration of sleep is from six to eight hours; it may extend even to ten hours for young children as well as for weakly persons,—being sensibly abridged among strong and sanguine men, or among excitable individuals, troubled with a nervous disposition,

the effects of which are neutralized only by exercise and labor. It is by devoting, one's self to these in a regular manner, by lessening the time given to repose, that we may hope to combat with any success that obesity which is the source of serious inconveniences, that sanguine condition which disposes to congestions, and that lymphatic plethora which leads to tuberculous diseases.

Sleep is not a function peculiar to the brain. Among reptiles the entire nervous system deeply experiences the influences of the periodical changes of the seasons; during hybernation, the functions of the life of relation are entirely suspended, and those of the internal life present only feeble and irregular movements. With man during sleep, digestion, respiration, and circulation are diminished. In this state he has a tendency to become cold, and congelation attacks him more readily than during the waking state. His faculty of producing caloric diminishes in the natural or normal sleep; but this refrigeration can only be carried on within certain limits, beyond which the sleeper awakens to fall into the abnormal or morbid sleep which may become fatal.

The subtraction of oxygen and caloric result, therefore, in determining sleep before death ensues. It may also result from asphyxia by drowning, from apoplexy, and from determination of blood to the head. Plethora is often announced by an invincible tendency to sleep.

Sleep, this rest of nature, this apparent nothingness, in which life is reanimated, in which all the functions are improved, as digestion, respiration, circulation, etc.—sleep, this repairer of our exhausted forces, must be regulated with the greatest care. If it be too prolonged, it weakens, it stupefies the body and mind; if too short, it does not sufficiently restore, and internal and febrile excitations soon destroy health. Unpleasant dreams announce a laborious digestion, an irritability or weakness of the nervous system, muscular fatigue, a greater or less determination to the brain, excitement of the brain, etc. Consequently, the person should eat less, drink fresh water freely, keep the bowels regular, avoid excess in everything, sleep on a moderately hard bed with the head slightly elevated, and with the body properly but not too warmly covered.

To retire to bed at an early hour, sleep seven or eight hours, and rise early in the morning, should be the rule of all persons desirous of preserving their health. However, this rule will not apply to all persons who are diseased, for with many, we will observe that after having awakened in the morning feeling no restoration from the night's rest, a sleep of one or two hours afterward will impart to them a feeling of strength and invigoration, which they would not

have experienced had they arisen upon their first awakening in the morning. Physicians should especially bear this in mind. The same rule will also be found to apply frequently to persons who are devoted to study or great mental exercise.

In our large cities where everything is inverted, the silence of the night is invaded, the bed is sought at the hour when one should be rising, and the sleep during the day gives a feverish repose, which no longer sustains nor invigorates the forces of the system, but which permits the organs to become impaired and disposed to the most serious symptoms.

The patient should carefully avoid these prolonged night sittings, for, as a general rule, the sleep of the first part of the night is the most agreeable, the most reparative; it is also the most powerful means of modifying, invigorating, and preserving life. The blood is refreshed, the brain is recruited, physical sufferings are extinguished, mental troubles are removed, the organism is relieved, and hope returns to the heart, under the influence of sleep in accordance with nature and the laws of health.

A large bedroom, well ventilated, if it be possible; a bed without curtains, and not soft but rather hard; a temperature rather cool instead of warm, so as to always have a respirable and vivifying atmosphere; covers according to their need; the head elevated; no clothing capable of obstructing the circulation; the stomach empty; the bladder and intestines evacuated; and the mind at peace; and the sleep will be that which it should be, the restorer of our forces, the moderator of life, and the guardian of health. In some diseases, a departure from a few of these rules may prove useful, as, in affections of the air-passages, where a warm air may be of more advantage than a cool one; but such cases are the exceptions to the general rule, and should not be permitted by the physician until he is fully satisfied of their necessity and propriety. Children, as a general rule, should never be allowed to sleep with persons somewhat advanced in years, and more especially if these are laboring under any form of disease. That injury to the health of a child who is permitted to sleep with an aged person is an almost invariable result, is well known to medical men. I have frequently treated children laboring under some anomalous disease which resisted all the remedial means employed to remove it, and, after having ascertained that they were in the habit of sleeping in the same bed with an older person, have had the satisfaction of seeing the affection gradually disappear, and without any employment of medicines, by causing them to sleep alone, or with some young companion.

I will make this one observation here, that when patients are subject to unpleasant dreams, and these gradually become changed, under therapeutical treatment, to pleasant ones, and especially if followed by a sense of refreshment upon arising, the physician may rest assured that his course toward the patient is the correct one.

BATHING.

In order that the capillary nerves and blood-vessels of the skin may be preserved in a healthy condition, it is highly essential that the whole surface of the body be bathed, at regular intervals, with some simple preparation which will remove the oily substance secreted by the sebaceous glands, as well as the perspiration discharged by the sweat glands, both of which concrete upon the surface of the skin, and within its numerous ducts, eventually occasioning some disease of the skin, unless they be removed by the bathing referred to above. Nor is this all; the sympathetic relations between the skin and the various internal organs are much greater than between those of any other organs of the body; so that in proportion to the derangement of the cutaneous functions will there be more or less derangement of these internal organs. When the skin is in a normal state, and performs its functions healthily, it removes an immense amount of effete matter from the system, and this excretory process may be carried so far as to frequently relieve the action of internal excretory organs when these are torpid or in a diseased condition, as, by causing increased perspiration, at various but regular periods; and, it must be recollected that, in the purest perspiration, there is a large amount of urea. But other influences are also effected upon the system by the application of cold or warm water to the surface of the body, according to the mode of application; thus, a tonic effect is caused by slight douches of cold or warm water upon certain parts, by which tone is given to both nerves and muscles; sedation may be produced by the continued application of cold water upon a part; stimulation, if hot water be used; relaxation, if the water be warm, etc. And these results may be so managed as to exert a beneficial influence upon internal organs which have lost some of their integrity. Hence, in the treatment of chronic diseases, an attention to the condition of the skin becomes a very important auxiliary therapeutical measure.

The various means employed for the purpose of maintaining a healthy state of the skin, and of aiding in the restoration of internal organs to a normal condition, are, bathings with soap and

water, bathings with an alkaline solution, cold, hot, or shower baths, and vapor baths.

For ordinary purposes of health and cleanliness, the whole body should be sponged with cool water, every morning, upon getting out of bed; the water should be applied quickly over the whole surface of the body and limbs, drying immediately with a coarse but moderately soft towel, and applying gentle friction with it at the same time, so as to cause a pleasurable glow. If this be not accomplished quickly, the evaporation of the water from the skin will cause a chill which may terminate in a severe and even fatal cold. As soon as the body is thoroughly dried, the person should at once cover himself, by dressing or otherwise, and either take a brisk walk in the open air, or some other kind of exercise to favor reaction. By the subtraction of caloric from the surface of the body, cold water at first chills; but to this primitive effect a contrary one soon follows; the organism, aroused by the cold water and the exercise, displays a powerful reaction of heat and life, from the center to the periphery. The skin reddens, the internal organs are relieved, the external circulation becomes more energetic and the respiration more free and lively. There is produced an operation of revivification, and of external stimulation, very favorable to the treatment and to the resolution of some chronic diseases. The system responds better to the influence of cool water in the morning, after a night's rest, than at any other time.

But this method alone will not invariably keep the skin in a normal condition; consequently the whole surface must be thoroughly washed with soap and soft water, using either brown or yellow soap, Castile soap, or petrolina soap. This regular bathing of the whole body should, as a general rule, be practised once a week in winter, and twice a week in summer. Oftener than this will produce too great an activity of the cutaneous functions, the evil results of which will be more especially felt in advanced age, the skin becoming harsh, dry, and very sensitive to external impressions, as well as being liable to some cutaneous disease. And if the skin loses its condition of healthy activity, the unhappy effects upon internal organs can very readily be seen.

Bathing with an *alkaline solution*, is more generally preferred for patients, than bathing with soap and water, because of its more readily uniting with the concrete oily matter discharged from the sebaceous glands, and more thoroughly cleansing the skin; but however valuable it may be in deranged or diseased conditions of this tegument, its constant use as a substitute for soap and water, in a state of health, would ultimately impair the cutaneous functions,

unless it were used much weaker than usually prescribed for patients. The alkaline solution is made either by adding about two drachms of Sal Soda or Saleratus to a quart of soft water; or by making a weak ley of hot water and hard wood ashes. If it be required to stimulate the skin, so that reaction may be more readily aroused, some alcohol or whisky may be added.

The frequency of these bathings, and also of the other baths hereafter referred to, as well as the temperature of the water employed, is, among patients laboring under disease, a matter of no small importance. It must be regulated by the physician, who will be governed by the character of the disease, the sensitiveness of the person to heat or cold, the condition of the skin, the strength, habits, and surrounding circumstances, as well as the reactive power of the system.

Cold bathing has a sedative or depressing influence upon the system, reducing the action of the heart and arterics according to the condition of the person; the advantages to be derived from it are due, not to the depression it causes, but to the subsequent reaction which ensues. Hence, whenever the temperature of the water is so cold that a chilly sensation continues for some minutes after its application, reaction coming on slowly instead of speedily, it is too cold for use, and will prove deleterious if persisted in. A warmer fluid must be used, whose sedative effect is not so powerful as to prevent a speedy reaction. For this reason, we recommend our patients to use cool, (60° to 75° F.); tepid, (85° to 90° F.); or warm water, (90° to 100° F.); instead of cold.

Local applications of cold water, in the form of lotion, bath, sponging, douche, or affusion, have, however, proved very efficacious in the treatment of external hemorrhages, burns, scalds, sprains, indolent ulcers, superficial cutaneous irritations, recent wounds, fractures, blows or bruises with infiltration of blood, ecchymoses, inflammations of the generative organs, strangulated hernia, hemorrhoids, chilblains, relaxation and paralysis of the eyelids, prolapsus of the rectum, leucorrhea and other discharges from the female generative organs, chronic ophthalmia with laxity of the vessels, etc. Continued irrigations have often succeeded in arresting the development of inflammation in complicated fractures. The same method, aided by a cold bath for the lower half of the body, has frequently been efficacious in cancerous irritation of the womb. I would remark here, however, that in cases where there is tension and considerable inflammation of the tissues, when the edges of ulcers are hard and callous, and also in wounds from fire-arms, tepid water should be employed in preference to cold.

Local tepid baths are also better for impressible persons, for those who are subject to constant perspiration which it would prove dangerous to suppress, in eruptive fevers, in complicated inflammations with irritation of the lungs, in cutaneous diseases, syphilis, nephritis, and also in cases where the body is exhausted by hard labor or a long walk. A douche of cold or tepid water has been frequently employed, with benefit, in apoplexy, affections of the head, determinations of blood to external parts, chronic external inflammations, muscular debility, impotency, etc.; and, when applied to the spinal column, has proved of great advantage in exhaustion, effected by excess of masturbation and abuse of sensual pleasures.

The *shower bath*, of either cold or warm water, is sometimes employed in the treatment of chronic disease, and with very excellent results; but it is not so generally useful as the other means of applying water, already referred to. A cold shower-bath should be avoided in cases where some internal organ is diseased, and with plethoric persons, as well as with those who are feeble and nervous. In these instances a tepid or warm shower-bath is preferable, if used at all.

Bathing, by immersing the whole body in water, is divided into sea-water baths, cold baths, and warm baths. The beneficial results obtained from *bathing in sea water* may be attributed not only to the stimulating influence of the water, but also to the vivifying action of the sea air, the influence of the light and sun, the mechanical, and perhaps electrical, motion of the waves, the promenades on the shore, and with children, their playing on the downs. But, in order that these immersions may produce truly salutary effects, certain rules must be observed: 1st. The bath should be taken in the forenoon, either before breakfast, or two or three hours afterward; no bath of any kind should ever be taken when the stomach is full, or is occupied in digesting food. 2d. A moderate degree of exercise should be taken before entering the water, but not sufficient to cause exhaustion, fatigue, weakness, or a too profuse perspiration. 3d. The clothing being removed, the person must immediately plunge the whole body into the water, and should remain in it until the bathing is finished. 4th. Three or four minutes is a sufficient length of time for the first bathings; but the time may be gradually increased to ten or fifteen minutes, provided there are no contra-indications. 5th. But one bath should be taken daily; in some cases, of very feeble or delicate persons, every second or third day will be often enough at the commencement. 6th. Immediately upon leaving the bath the person should thoroughly dry his body, or, if too weak, have an assistant do it; then dress without delay,

and afterward take a short walk or some other gentle exercise. 7th. If reaction does not readily come on, some mild stimulant may be given to facilitate it, and at the next bathing the patient must not remain in the water so long a time as before; or it may be necessary to suspend the bathings for a time.

After plunging into the sea, the body should be kept as much as possible in a horizontal position, that it may be subject to the action of the waves, which will give a favorable impulsion to it; then return to the shore, dry with care, dress, and promenade. Under the influence of these baths, the indications of improvement will soon manifest themselves; the vivified skin loses its paleness and softness,—it becomes more or less red; the capillary vessels are developed,—a richer blood having restorative principles circulates in them. The morbid embonpoint gradually disappears; the muscles become more prominent; the character acquires a greater degree of gayety, the will becomes more energetic, and the mind more active. When these important modifications occur in the system, we may then order two baths daily.

Sea bathing is very serviceable as an auxiliary for young persons whose organic texture is soft, constitution weakly, and whose organs are slowly developed at the period of puberty. It is also useful in many cases where menstruation does not readily manifest itself; in relaxation of the ligaments of the womb; in leucorrhœa, and even in sterility, females have occasionally become fruitful by its employment. It has likewise been successfully prescribed in chlorosis, in which malady, if the debility will not permit the use of entire baths, sitz baths of sea water, in which the lower half of the person is immersed, may be substituted, and their influence be seconded by moderate exercise in the open air; in convulsive, hysterical, and epileptic affections, as well as in other nervous diseases in which atony predominates over irritation,—in which cases sea water may be employed in baths, affusions, or douches; in hypochondria, melancholy, and mania, in which these different modes of application have been equally successful; in chorea, diseases of the skin, eruptions of various kinds, indolent and scorbutic ulcers, gastric cough, and affections of the stomach which accompany an increased acid secretion; in impotency, exhaustion from abuse of sensual pleasures or excess of masturbation, chronic fever and agues, obstinate catarrhs, mucous discharges from the vagina or rectum, pituitous cough, etc. Bathing in sea water has likewise been found especially beneficial in scrofula, and diseases of a scrofulous character, rickets, chronic affections of the liver, spleen, and stomach, glandular obstructions, non-malignant tumors, derangement of the kid-

neys, leprosy, jaundice, some kinds of debility, etc. Its effects usually appear more promptly among children than among adults. Internally, sea water acts as an excitant and resolvent, and aids materially in the resolution of engorgements of the lymphatic system. Children may take it in spoonful doses, and adults by tumblerfuls. In doses of a quart or more it has a purgative effect.

Sea bathing should not be prescribed in acute affections of the nervous centers, of the brain and spinal marrow, plethora, tendency to congestion, febrile action and inflammation, especially inflammation of internal organs, in certain cutaneous diseases, hemorrhage from the lungs, and consumption; the sharp air of the sea rather accelerates than retards the progress of phthisis.

Bathing in cold soft water requires an attention to the same rules as named above for sea-water baths: but its effects are less stimulating. When the body is in motion while immersed in cold water, as in swimming, the results are much more beneficial than when, as in an ordinary bathing tub, the body remains immovable. It has been thoroughly demonstrated by experiments that the cold bath is debilitating, and that the subtraction of the caloric which it occasions, may, in this respect, be likened to the results of bleeding; it is only when we limit its duration, and employ it consecutively, that it acquires an opposite action. The physiological effects of the cold bath should be well understood by the physician. They are: 1st. Constriction of the tissue of the skin; 2d. Slowness of the capillary circulation at the periphery; 3d. Diminution of temperature; 4th. The more or less complete arrest of perspiration. But, when reaction comes on, we see the tissues dilate and regain their natural color, the circulation becomes more active, the heat more considerable, and the perspiration more abundant.

Cold baths act differently upon persons who use them, according to their temperament, age, and even certain organic conditions which are not dependent upon strength nor debility. With many the desired reaction comes on promptly; with others, the reaction comes on slowly, is imperfect, or is insignificant. The parts immersed in the bath remain cold for a long time, and heat, to any extent, is only manifested after the skin has been excited by frictions, exercise, and warm clothing. The reaction, then, is not due to the cold bath, but to a vital movement effected naturally or by artificial means.

We can not lay down any invariable rules for the use of baths; there are some persons who can bear cold much better than any other baths. But the contrary happens more frequently, and those constitutions which, without being feeble, react with difficulty

against cold, should not employ baths at a low temperature, lest fatal congestions be the result. If the physician should prescribe them, he must always order them to be followed or accompanied by energetic frictions, or exercises which will recall the heat and perspiration to the surface. And even notwithstanding these salutary precautions, the untimely suppression of the perspiration very frequently gives rise to boils and to deposits beneath the skin, which the followers of hydropathy, not knowing their origin, have termed *crises*.—As a general thing, cold baths are of much less value in chronic disease than warm; for cold water is rather a preservative than a curative means, indispensably requiring for its auxiliaries, exercise, free air, and light. Reduced to itself, its circle is limited, its mission sterile, its effects accidental and often serious.

A *warm bath* occasions agreeable and refreshing sensations, softens and relaxes the skin, causing a more free and easy circulation of the blood in the capillary vessels, as well as permitting a more thorough removal of impurities from the surface of the body; it tranquillizes the nervous system, lessens increased action of the heart and arteries, invigorates all the internal organs, equalizes capillary circulation, and improves respiration. It is of great utility in many chronic diseases, in spasmodic affections of the bowels, convulsions of children, gravel, hernia, rheumatic and neuralgic affections, and in many cutaneous diseases. It is of especial benefit to children, nervous and delicate persons, the aged, and those with whom the vital powers are feeble. The duration of a warm bath should be from five to twenty or thirty minutes, according to its effects upon the system. The idea that persons taking warm baths are liable to contract colds, and require stimulants to prevent it, is an erroneous one; warm baths are not more apt to be followed by colds than cold ones.

Baths may frequently be rendered more efficacious for certain diseases, by dissolving in the water composing them some medicinal agent which, from its absorption or local action upon the surface, will produce healthful influences. Such are called *Medicated Baths*, of which there are several kinds. Thus, four ounces of sulphuret of potassium, and one ounce of diluted sulphuric acid, added to thirty gallons of water, forms a *Sulphur Bath*, useful in many cutaneous diseases, rheumatic affections, hepatic disease, secondary syphilis etc.

A very excellent *Sulphuretted Bath* may be prepared as follows: take of Sulphuret of Potassium or Sodium, three ounces; Carbonate of Soda, two drachms; Chloride of Sodium, two drachms; Sulphate of Soda, one ounce; distilled water, one pint. Mix, and when the

several salts are dissolved, pour it into twenty gallons of water at 98° or 100° F.

A *Nitro-Muriatic Acid Bath*, very useful in diseases of the liver and spleen, constipation, syphilitic eruptions, etc., is made by adding to thirty gallons of water, at 90° F., from thirty to forty fluid-ounces of a mixture of three parts, by measure, of hydrochloric acid and two of nitric acid; it should be used only in a wooden bathing tub.

An *Iodine Bath*, employed in scrofulous affections, cutaneous diseases, and tuberculous maladies generally, is composed of Iodide of Potassium, one drachm and a half to six drachms and a half; Iodine, forty-five grains to three drachms and a quarter; water, ten fluid-ounces. Dissolve, and add to a bath containing sixty gallons of water. The milder strength is for children and weakly adults.

Various other Medicated Baths, as Aromatic, Iodide of Iron, Sulphuretted, etc., have been highly recommended; but they usually require considerable apparatus and attention, and are too expensive for practitioners in ordinary practice, and hence are rarely employed, except in hospitals, or by those who make their use a speciality. However, although they may and do prove beneficial in the removal of many of the diseases for which they are used, their employment may, in the majority of chronic diseases, be dispensed with, the remedial measures hereafter described being, as a general rule, found much superior to them in efficacy and permanency of cure.

I must, however, make an especial exception here, for in the treatment of secondary and tertiary syphilitic affections, I have derived immense benefit from the Sulphur and Iodine bath combined.

Electric Baths have been much employed of late years; the vital forces are said to be increased by the electro-positive bath, and diminished by the electro-negative. In giving an electro-positive bath, the electricity accumulated upon the glass plate must be collected, while the negative electricity, acquired by the cushions or rubbers from the friction, must be disposed of as rapidly as it is liberated; to effect which a metallic chain must be attached to the cushions between which the glass plate or cylinder is turned, and then be made to communicate with the ground. The patient being seated upon an insulating stool, is requested to hold the prime conductor of the electrical machine in his hands, and the machine is then put in motion. The whole surface of the patient's body becomes charged with positive electricity, while the air surrounding it is rendered negative. A bath of this kind should be used for

about three hours each day; it is useful in conditions of the skin and mucous membranes where there is deficient action. In giving an electro-negative bath, the negative electricity accumulated upon the cushions must be collected, while the positive electricity acquired by the glass plate or cylinder must be passed off as rapidly as it is liberated; to effect which, a metallic chain must be made to form a communication between the glass plate and the ground. In this bath the cushions should be insulated by means of glass supports. A bath of this kind is said to have a debilitating effect, reducing the pulse, and has been used in erysipelas, headaches, neuralgia, and all chronic inflammations.

The *Galvanic Bath* has been found useful as a stimulus in paralysis, in scrofulous affections of the joints, etc., in the muscular atrophy of children, in rheumatism, and indeed in all diseases where there is pain or a want of tone. "The bath itself may be of any form or material; if, however, it is of unpainted metal, it must have a sheet put in so as to line it, that the body of the patient do not touch the metal. It should be filled with the necessary amount of water, of a suitable temperature, into which may be placed any salt or drug which may be deemed necessary, as bay salt, acetic acid, etc.—A Pulvermacher chain, made expressly for the bath, of sixty elements, excited in the usual way, by being drawn through pure vinegar, should be hung up by the hook at the positive pole, to the wall, by means of a piece of string, of such a length as to allow the negative or white pole to enter the water, but not any part of the chain; the chain should also be free, and not touch the bath, sheet, wall, etc., except where mentioned; by the means of a wire attached to the hook at the positive pole, a conductor, containing a moistened sponge, can be placed upon any portion of the patient (who has been placed in the water); a current now passes into the body at the positive conductor, issuing out at every pore into the water. Of course there are many ways of availing one's self of the galvanic bath; the whole body may be inserted, or merely the hand. There is no shock experienced except upon first placing the conductor upon the patient, then a slight tremor pervades the system, after which nothing is experienced.—A genial glow soon appears, and an exhilaration of spirits, the secretions freed, and tone sooner or later, according to the case, is the result. The galvanic bath may be resorted to at any time when a person may not feel in his usual health, during an epidemic for instance, when the electrical state of the atmosphere is not in its usual state." *H. Lobb.*

There are other methods of using the galvanic bath, but the above

is the most convenient and easiest of application, as well as the cheapest.

The *Spirit Vapor Bath*, or *Hot Air Bath*, is another method of acting upon the skin, and through this upon internal organs. It exerts a most powerful, yet beneficial influence upon the whole system, aiding very materially our endeavors to throw off disease. This bath is valuable in nearly all chronic diseases, in which it may be used once or twice a week, or once a fortnight, according to indications or the strength of the patient. Where it can be done, it is always preferable to bathe the patient with an alkaline wash before taking the vapor bath; and three or five hours after the perspiration caused by it has subsided, with a mixture of three gills of water, one gill of alcohol, and half a table-spoonful of salt.

The advantages to be derived from this method of producing perspiration are very great, and it is not followed with any of those injurious consequences which often attend the internal administration of a sudorific. It is to be given as follows: The patient is undressed, ready for getting into bed, having removed the shirt and underclothing worn through the day, and put on a night-shirt or other clothing to be worn only while sweating, and during the night, if the bath is taken at bed-time. He is then seated on a high Windsor, or wooden-bottomed chair, or instead thereof, a bench or board may be placed on a common open-bottomed chair, care being taken that the bottom is so covered that the flame will not burn him; after seating himself, a large blanket or coverlid is thrown around him from behind, covering the back part of his head and body, as well as the chair, and another must be passed around him in front, which last is to be pinned at the neck, loosely, so that he can raise it and cover his face, or remove it down from his face from time to time, as occasion requires, during the operation of the bath. The blankets must reach down to the floor, and cover each other at the sides, so as to retain the vapor and prevent it from passing off.

This having been done, a saucer, or tin vessel, into which is put one or two table-spoonfuls of whisky, brandy, spirits, alcohol, or any liquor that will burn, is then placed upon the floor, directly under the center of the bottom of the chair, raising a part of the blanket from behind to place it there; then light a piece of paper, apply the flame to the liquor, and as soon as it kindles let down the part of the blanket which has been raised, and allow the liquor to burn till it is consumed, watching it from time to time to see that the blankets are not burned; as soon as consumed, put more liquor into the saucer, about as much as before, and again set it on fire—being careful to put no liquor into the saucer while the flame exists, as there

would be danger of setting fire to the blanket, and producing injury to the patient. Continue this until the patient sweats or perspires freely, which, in a majority of cases, will be in five or ten minutes.

If during the operation the patient feels faint or thirsty, cold water must be sprinkled or dashed in his face, or he may drink one or two swallows of it—and in some cases the head may be bathed with cold water.

As soon as free perspiration is produced, wrap the blankets around him, place him in bed, and cover him up warm, giving him about a pint of either good store tea, ginger, or some herb tea to drink, as warm as he can take it. After two or three hours, remove the covering, piece by piece, at intervals of twenty or twenty-five minutes between each, that he may gradually cease perspiring.

There is no danger of taking cold after this spirit vapor bath, if the patient uses ordinary precaution; and if his disease will allow, he can attend to his business on the next day the same as usual. In fact, the whole is a very easy, safe, agreeable, and beneficial operation, much more so than a mere reading of the above explanation would lead one to suppose.

Patients will sometimes be met with in whom it will be almost impossible to produce even a slight moisture of the surface, much less visible perspiration. The skin of such persons is generally dry and harsh, frequently scaly, imparting an unpleasant sensation to the touch. In most instances, the skin may be restored to its original normal condition by adopting the following course: 1st. Anoint the whole surface of the body and limbs with olive oil every night upon retiring to bed. 2d. Every morning wash the whole surface of the body and limbs with a warm, weak alkaline solution, employing considerable friction while drying. 3d. Every two weeks administer a spirit vapor bath. A perseverance in this course, for a few months, will accomplish the desired result.

LIGHT.

Whatever others may consider light and heat to be, I am firmly of the opinion that they are the results of action of the electrical rays or emanations of one body upon those of another. Thus, the galvanic or electrical rays of the sun acting upon the electrical atmosphere, as well as upon the magnetic substance of our earth, give rise to both light and heat. When one surface of a planet is not directly exposed to the solar electrical rays, or to the rays emanating from some other body or bodies, darkness and cold exists, and continues until those rays act upon it. And the denser the body or its atmosphere, the greater will be the degree of light or

heat produced, in proportion to the galvanic power of the rays influencing it.

Light, heat, and electricity, under its various modifications termed magnetism, galvanism, etc., exert an exciting influence upon our several organs, and sustain their functions through the agency of the nervous system. In consequence of the atmospheric air or oxygen absorbed in respiration, both man and the superior animals develop a great amount of caloric; under the same influence certain kinds of fish transmit true electrical currents, and several insects produce light.

Generally, the effects of light are the more remarkable as the organized beings upon which it acts are of a more inferior order. The expansive and vivifying impression of this agent gives vitality to plants in the spring, through which they become adorned with handsome verdure, develop their leaves, and expand their flowers. This fecundity is lessened or destroyed if the plants be placed under cover, so as to deprive them of the action of light, as may be seen in forests where the larger trees cause the smaller ones to perish or become dwarfish by depriving them of light. The dwarfish trees become deformed and stunted in growth; their fruits are scanty, abortive, tasteless, and without beauty. This is not due to the absence of the atmospheric oxygen, but to a deficiency of light. For how constantly do we observe plants exposed to the air, but deprived of the benefit of the solar rays, lose their strength, their properties, and their growth?

Inferior animals are subjected to the same laws, and in severe weather a large number of animated beings perish for want of light, or rather for the want of the caloric produced by electrical action. It must be borne in mind that these two agents, light and heat, blend their action in certain cases, while in others the action of each is isolated and distinct. The action of caloric is purely exciting, while that of light contributes more particularly to the organization, or to the regular development of the organs. Experiments have demonstrated that, in this relation, light has an influence independent of heat. M. Edwards, sen., having placed some frogs' eggs in vessels filled with water, one of which was deprived of light by covering it with black paper, and then having exposed the vessels to an equal temperature, observed that the eggs in the transparent vessel successively developed themselves under the influence of the sun's rays, while those in the darkened vessel were rendered abortive.

Light may be considered as imparting a vital stimulus to the organized world, promoting the development of organs, and the

nutritive processes of plants; the green color of vegetables is due to its action. The light during morning appears to exert a much better influence upon organized beings than that of the latter part of the day. The younger the persons the more need have they of exposure to the light; those nations who sleep in tents and exercise in the open air from childhood, are usually of high stature, with great muscular strength, and much regularity and beauty of form.

An absence of light disposes to inactivity, somnolency, smallness in stature, anæmia, rickets, scrofula, debility, œdema, etc., and is only temporarily beneficial in cases where there is great vascular or nervous excitement, as, in active forms of insanity, excessive mental irritation, irritable or inflammatory conditions of the brain, eye, or nervous system generally, wakefulness, restlessness, etc.

The prolonged action of light will not only prevent deviations of the osseous system, but, by exciting perspiration and preserving permanent activity of the functions of the skin, will ward off attacks of scrofula and of phthisis, and prove exceedingly beneficial in the treatment of most chronic affections. Insolation, or an exposure to the rays of the sun is resorted to in some countries for the purpose of arousing the vital powers when depressed or languishing, as, in cases of extreme feebleness, paralysis, indolent ulcers, etc.

In certain diseases of the eyes, too strong a light, or even any light at all falling upon these organs, will greatly aggravate them, in which cases the eyes must be properly protected, not only from the full action of light, by colored spectacles, shades, etc., but also from sudden transitions from darkness to light, and *vice versa*.

HEAT OR CALORIC.

This material principle of life is formed in living bodies by the act of breathing, in which it is the result of the oxygenation of the blood as well as of the combinations to which this chemical action gives rise. Excessive cold, in which the animal heat is nearly all absorbed, is followed by congelation and gangrene. The development of the vital movements of plants and animals, especially among those of an inferior order, are retarded or suspended by the action of cold. A moderate degree of cold induces sleep. As an opposite result of the same principle, the natives of very warm climates have the periods of puberty, turn of life, old age, and death to occur at an earlier age than the natives of temperate regions.

Heat, at a certain temperature, is a stimulant of a vivifying char-

acter, and is absolutely necessary for the preservation and continuance of life. If increased beyond this temperature, it becomes a cause of excitement, exhaustion, and disease. The most robust will have their constitutions enfeebled by the profuse perspiration it gives rise to. At a still higher temperature, heat is destructive to vital action.

Patients laboring under chronic diseases should always be kept comfortably warm by the proper amount of clothing, and should guard against cold, especially of the feet, the back, and the armpits. The rooms they occupy should also be kept at a temperature not too high, but which should be regulated by the feeling of comfort and warmth they experience when not in motion. Too much warmth favors debility and retards a cure.

ELECTRICITY.

Electricity pervades all matter, existing either in a latent or unperceived state, or in a free and demonstrable condition. Its action upon matter produces various results, known as mechanical, luminous, calorific, chemical, magnetic, or physiological.

Electricity, Magnetism, and Galvanism are but modifications of the same force or agent. When at rest, or in a state of equilibrium, it is called *static*; when in motion it is termed *dynamical*.

Static or frictional electricity is always small in *quantity*, but in a state of high *tension* or elasticity, and possesses a very feeble chemical action; the sparks drawn from a common electrical machine are very large, in consequence of the small *quantity* of the fluid and the high *intensity*.

Dynamic electricity, under the forms of galvanism and electro-magnetism, results from a decomposition of the natural electricity of the material employed and the liberation of active electricity; it is always large in *quantity* but of very low *intensity*, and is very powerful in effecting chemical decompositions; its sparks, even from very large batteries, are very small.

Although frictional electricity has sometimes been serviceable in the treatment of disease, it has not proved so generally applicable and efficacious as galvanism and electro-magnetism, which may be considered the true medical electricity. Indeed, I believe that for therapeutical purposes static electricity can be entirely dispensed with. Some forms of disease may be permanently cured by dynamic electricity, and without any internal medication. In a large number of cases, however, internal remedies will be required in addition. When the current is properly applied to diseased

organs, it tends to render them more susceptible to the action of the medicines administered, thereby expediting the cure.

Electricity is supposed to be composed of two contrary forces or fluids, which are called positive and negative electricity; and the points or materials from which these forces are given off are termed *poles*—there being a *negative* pole, and a *positive* pole. In the ordinary voltaic pile the zinc forms the positive pole, and is at the top of the pile, while the copper forms the negative, and is at the bottom. In the decomposition of water by the galvanic pile, its oxygen is always attracted to the positive pole, and its hydrogen to the negative.

In the constant batteries, however, where the metals are plunged into separate vessels, the current assumes a different direction, so that the zinc forms the negative pole, and the copper or platinum the positive.

Any substance whose component atoms are all alike, or as much so as possible, and closely arranged or packed together, will permit the electrical currents to pass rapidly through them, and are termed *conductors*. A greater or less degree of resistance to the passage of an electrical current is presented by all conducting bodies, in consequence of which the intensity of the current is diminished according to the degree of resistance. Metals are the best conductors, and their conductibility ranks as follows, the best being the first named: Silver, copper, gold, iron, platinum, lead, and mercury, which is the worst conductor of them all.

A substance whose atoms are irregular, or of different capacities, and loosely arranged or packed together, does not permit the electric force applied to it to be readily conveyed from one of its atoms to the other, and forms a *non-conductor*. Hence glass, caoutchouc, wood, dry air, etc., are termed non-conductors. Fluids are worse conductors than metals; elevation of temperature, however, increases the conductibility of the former, and lessens that of the latter.

The human body is a conductor of electricity, the greatest resistance to the passage of the current being offered by the dry epidermis. If the epidermis be moistened with salt water, this resistance will be much diminished; much more so if the fluid be warm; and entirely so if the epidermis be removed at that part to which the electrode or conducting wire is applied.

When one electrified body exerts an influence upon another conducting body, inducing an opposite state of electricity in the latter, although this last may be separated from the other by a non-conducting medium, this action or power of electricity is termed *induc-*

tion. Thus, if a non-magnetized bar of iron be held perpendicular to the earth, it will immediately acquire magnetic properties, and the magnetic needle, upon being applied to it, will show that the lower part of the bar is in an opposite state of electricity to that of the hemisphere in which the experiment is tried, while its upper end will be in the same electrical condition as the hemisphere. The bar of iron is now said to be magnetized by induction from the earth. When electricity is induced by the influence of other electricity, it is termed "electro-dynamic induction," or "electro-magnetism;" when induced by the influence of magnetism, it is called "magneto-electric induction," or magneto-electricity.

The terms *quantity* and *intensity*, as applied to voltaic or galvanic currents, have the following meaning: A current formed by a single pair, (or one plate of zinc and copper,) if passed through short and thick wire, connecting the two poles, will be great in quantity; but if the current be produced by a pile consisting of a number of pairs, whose elements present the same amount of surface, taken together, as the single pair, and the poles of this pile be connected by a long, fine wire, there will be the same quantity of electricity as in the former case; but, in passing through the fine wire, the electricity must necessarily be in a state of greater *density* or *tension* than that which passes through the thick wire, and these differences in the density of the voltaic currents are comprehended by the terms of quantity and intensity. (*Althaus.*)

The discovery of magnetism by induction, viz., that soft iron, when surrounded by a helix of copper wire covered with silk or other insulating substance, becomes powerfully magnetic while passing an electric current through the wire, led to the introduction of electro-magnetic instruments, many forms of which have been manufactured and presented to the profession for the treatment of disease. Some are electro-magnetic or volta-electric, and the others magneto-electric, and each give out what are termed, "interrupted induced-currents," or "interrupted currents of induction."

The electro-magnetic instrument is that in which the current is induced by a single galvanic pair, by the action of acids or other decomposing fluid; and although it is somewhat more troublesome to the practitioner than the magneto-electric instruments, yet it furnishes a much larger quantity of electricity than these last, the current of which is possessed of physiological and therapeutical properties not exactly the same as that induced by a permanent magnet of steel, and which acts more especially on the motor nerves and muscles, and the sentient nerves.

The magneto-electric instrument is that which is put into opera-

tion merely by the turning of a handle, which rotates a soft-iron armature before the two poles of a fixed horse-shoe magnet, causing magnetization and demagnetization of the soft iron, from which sudden changes in its condition, electric currents are produced, the intensity of which depends upon the power of the permanent horse-shoe magnet, the diameter of the wire wound around the armature of soft iron, the number of convolutions of the wire, the distance of the armature from the poles of the magnet, and the velocity with which the wheel is turned. The objections to this instrument are, that it frequently gets out of order, that the permanent magnet in time loses its magnetism and requires to be remagnetized, and that an assistant is generally needed to turn the handle.

The medical man who employs electricity in the treatment of disease should possess both sorts of induction machines; the volta-electric for neuralgia, paralysis, etc.; and the magneto-electric for defect of vision, and for the absorption of rheumatic callosities. Every electro-magnetic apparatus designed for medical use must furnish two induction currents, viz.: the primary and the secondary, as sometimes a current of low tension may be required, and at others one of high tension. The electro-magnetic instruments manufactured by Jas. Foster & Co., of this city, are arranged so that the operator may employ either the primary or secondary current, as he may prefer.

The first or primary wire of the helix (bobbin of induction) of an electro-magnetic instrument has its extremities connected with the poles of the battery; as the inducing current generally proceeds from a single pair, this wire must be somewhat short and thick, in order to present but slight resistance to the passage of the current so that it may produce a powerful electro-magnet. In addition to the inducing current of the battery, there is another and stronger current developed in the short, thick wire, which is owing to the spirals (coils) of the wire, when very close together, acting mutually upon each other,—so that the spirals serve both as inducing body and as induced body. This current is called the “*primary current*,” “*extra current*,” “*direct current*,” or “*current of the first order*,” and occurs both when the circuit is broken and at the moment of its re-establishment. The direction of this current is opposite to that of the battery current on *closing* the circuit, and is equal to it on *opening*. If a piece of soft iron be introduced into the helix, the energy of this current will be greatly augmented; it gives out sparks, shocks, and heat, and will decompose water. The primary current is, therefore, the result of induc-

tion by its own spirals and by the temporary magnet; its action is chiefly on the contractile power of the muscles, because of its comparatively low tension.

The current induced in the second wire, which is long and fine, is due to induction by the current of the battery and by the electro-magnet, and is termed the "*secondary current*," "induced current," or "current of the second order;" its direction is quite equal to that of the primary current, and like this current, it is the most powerful on *opening* or establishing the circuit. The secondary current acts chiefly upon the nerves of sensation and on the retina; it possesses a higher degree of tension than the current induced in the short and thick wire.

If, in a closed circuit, two points are connected by an additional conductor, a derivation of the current is brought about. The current, as it existed before the derivation was made, is termed the primitive current; the additional conductor, derivation wire, and the portion of the current that passes through this wire, is called the *derived current*. (*Althaus*.)

The intensity of the currents induced by voltaic electricity depends upon the intensity of the inducing current of the battery, the transverse section and the number of convolutions of the wires, the current being stronger according to the length and fineness of the wire, and upon the more or less insulated state of the soft iron placed within the helix.

Induction currents differ from the continuous galvanic current in this respect—the latter always moves in the same direction, while the former move alternately in different directions. Hence, in the electro-magnetic, and magneto-electric apparatuses there is no permanent positive or negative pole, and for physiological or therapeutical purposes it is therefore immaterial which of the conducting wires or electrodes is placed at any given point. But it may be well enough to recollect that both the primary and secondary currents are much more powerful on *opening* the circuit than on *closing* it, and have at the same time a direction equal to that of the inducing current of the battery; therefore, in employing induction currents, those only should be regarded which are induced on opening the circuit.

The negative pole of a galvanic pile, and of induction machines, has a stronger effect on the nerves of the skin than the positive pole; consequently, the negative pole may be readily distinguished by the stronger sensation it excites; but for this purpose the size and condition (moist or dry) of the conductors or electrodes must be equal, and the parts of the skin acted upon should be of equal

thickness, also containing, as nearly as possible an equal distribution of sentient nerves.

In honor of Professor Faraday, of England, whose untiring efforts and investigations have brought the subject of electricity to its present elevated position in science, the term "Faradaic electricity" has been adopted to express electro-magnetism, or magneto-electricity; also "Faradaic currents," to signify induction currents; and "Faradization," as designating the localization of induction currents to a single muscle.

The instruments for the purpose of making therapeutical employment of the continuous galvanic current are *Daniell's Batteries*, and *Pulvermacher's improved chains*. The Galvanic bath has already been referred to. When Daniell's Battery is used, a continuous current may be sent through the body, by filling two vessels with salt water and connecting them separately with the poles of the battery; then, if the patient immerse one hand or foot in one vessel, and the other in the second vessel, the current will pass through the limbs and body from one pole to the other.

If it be desired to localize the continuous current in certain parts of the body, insulated directors or excitors are employed, the extremity of one of which must be connected with the negative pole of the battery, and the extremity of the other with the positive pole; the free extremities of each must be covered with moistened sponge or flannel, to be applied to the desired points on the body.—To practice *Electro-puncture*, attach two fine platina needles at the free extremity of the directors or conductors, in place of the flannel or sponge, and introduce them into the tissue to be acted upon.—If the *galvanic cautery* is to be used, the instrument invented for this purpose by Professor Middeldorpf, of Breslau, or the one by Mr. Ellis, may be attached to the free extremity of the conductors, and then applied, *secundum artem*, to the part requiring cauterization.*

* Professor Middeldorpf's galvanic cautery consists of a wooden handle composed of two lateral halves which can be separated from each other; this is traversed its whole length by two gilt copper wires, by which the current is conveyed. One of these wires is divided into two halves; if these two halves be separated from each other, there is no action of the current; but by uniting them, which is easily done by a screw, the circuit is established. At their posterior extremities the wires are connected with the poles of the battery; while at the anterior end a platinum wire is inserted, which is rendered incandescent as soon as the circuit is established. To this platinum wire different forms may be given, according to the shape of the tissues upon which we desire to act. This instrument, while cold, may, therefore, be introduced into a cavity. When it is in its

In those cases where it is desirable to produce a continuous current of galvanism, and without the intervention of conductors or electrodes, there is no instrument superior to *Pulvermacher's improved galvanic chains*. The principle upon which these are made is as follows: thin zinc wire is wound around a small rod of wood; one end of the wire entering the wood, the other end terminating in a loop or ring. At the opposite end to the zinc loop there is a loop of thinner copper wire, which winds round the rod in the interspaces of the zinc wire, and enters the wood at the opposite end. This forms one element, which, in order to form a chain, is attached to another element, and this to another, and so on, until as many elements are connected as may be required. But in order that a galvanic current may be produced, each link or element must be properly connected with its fellow, that is, the zinc ring of one must be in contact with the copper ring of the other, and its copper loop with the zinc loop of this, and which mode of attachment must be kept up among all the elements forming the chain. At one end of this chain the zinc wire is free, forming the positive pole; at the other end the copper wire is free, forming the negative pole.

When these chains are immersed in vinegar, the wood is impregnated with the fluid, and the action of the battery is excited, and a steady current of galvanic electricity is kept up. This chain gives out electricity of high tension, and in sufficient quan-

right place, the circuit is made by uniting the two parts of one of the conducting wires; and if the cauterization is to be discontinued, the circuit is broken by separating the two parts of that wire; after which the instrument may be removed without injury to the parts.

Mr. Ellis's instrument is described in the *London Lancet*, vol. II, p. 502, 1835, and is designed to cauterize a considerable surface. A straight silver catheter, with the end cut off, forms the body; at its upper end the catheter is slit open and broached, so as to form a socket for the porcelain cauterizer. Within this catheter are placed two conducting wires which connect with the poles of a battery; the free extremities of these wires connect with a piece of platinum wire, which is coiled around the porcelain pencil in order to heat it to whiteness. This may be employed in induration of the os and cervix uteri, in ulceration of the os, prolapsus uteri, prolapsus of the anterior wall of the vagina, fissure of the anus, etc. A glass speculum is first introduced into the vagina; the os is then cleansed with a piece of wool, the cautery heated and quenched in the diseased tissue; the duration of the application and the depth of its introduction depending upon the effect required. Eschars are readily produced, and the cervix uteri is often seen to contract under the application of the cautery. Four pairs of Grove's battery are sufficient to render platina wires incandescent, but it is essential that the plates of the battery should possess a large surface, in order to liberate a large quantity of electricity. (*Althaus*.)

tity for almost any medical purpose. Six links will yield sufficient electricity to decompose water into its component gases. These chains are very useful in many nervous disorders; muscular debility; hemiplegia; paralysis of children, and atrophy from wasting of the anterior roots of the spinal nerves; general progressive muscular atrophy of children; central or cerebral paralysis; spinal paralysis; neuralgia; sciatica; stiff joints; œdema of the limbs; hysteria; hysterical paralysis; aphonia; epilepsy; torpid liver; asthma; amenorrhea; dysmenorrhea; spinal irritation; nervous debility; constipation; deafness not due to actual disease or structural change; rheumatism; dyspepsia; paralysis of the bladder; chorea; impotency; writer's cramp; hysterical cramps and contractions; loss of smell; loss of taste, etc. As the chains have a very remarkable action on the retina, they should be applied with caution to the face, and should not be used at all in amaurosis.

M. Pulvermacher has also invented an instrument which he calls the Electro-Physiological Modifier, which, when attached to the chains, enables the operator to interrupt and renew the current at will, or to produce rapid vibrations. He has also invented a most perfect apparatus, termed the Galvanic Chain Band, which can be adapted to any part of the body or limbs.

These chains and bands may be used apart from the body by means of conductors; but more generally they are worn next the body, keeping up a continuous current of galvanic electricity. They are used of various powers, from five to two hundred and forty elements.

Galvanism may be applied in several ways, as—1. With the hand; 2. with conductors; 3. with *metallic wires*.

1. When patients are extremely sensitive to galvanic action, the operator holding one conductor, has the other applied to the sensitive part, and, having previously well dried the skin of the patient, he passes the fingers, also dry, of the hand not occupied in holding the conductor over the surface of the patient's body, or of that part of it intended to be acted upon.

2. When we desire to *localize* the electricity in the skin, and the terminal extremities of the cutaneous nerves, it is effected by thoroughly drying the skin, and then placing one dry metallic conductor upon the affected part, or near it, and the other metallic conductor, also dry, upon a part somewhat distant from the affected region.

If, however, we desire to penetrate to the internal organs, muscles or nerves, the skin, as well as the metallic conductors, should be well moistened with salt water.

In stimulating a paralyzed muscle, a pointed metallic conductor, covered with moistened sponge, should be used, as we are thus enabled to search out any particular muscle, and stimulate it individually. Some of the deeper muscles are not easy to get at, and it requires some anatomical knowledge to discover the point where the motor nerve enters the muscle, upon which spot the conductor should be placed.

3. Metallic wires, or a wire brush, is sometimes required, as in paralysis of sensation of the surface; they are to be applied in the same manner as the metallic conductors.

The galvanic current enters the body at the positive or zinc pole, and is removed at the negative or copper, so that a current may be directed from the center to the circumference, and vice versa. In stimulating nerves of sensation the positive pole must be placed at the periphery, the negative at the center, and the current must be interrupted. In soothing nerves of sensation, the direction must be the same, but the current must be continuous. In stimulating nerves of motion, the positive pole must be placed at the center, the negative at the circumference, and the current must be interrupted; in soothing, the current must be in the same direction, but continuous.—In cases where a continued supply of the galvanic stimulus is required, the method of proceeding is,—after the muscles have ceased to respond to the stimulus, alter the situations of the poles of the battery; place the positive pole where the negative was before, and vice versa, the muscles will immediately respond to the fresh stimulus. This is founded upon the rule laid down by Matteucci,—“The electric current restores the excitability of a nerve which has been exhausted by a reverse current.” (*H. Lobb.*)

The subject of galvanism in its therapeutic applications is one of great interest, and occupies an extensive field; it is impossible to do it anything like justice in the present work, further than to refer to it in the same manner as to other remedial agents, for instance, jalap, rhubarb, etc., which are more especially described in *Materia Medica*, etc. Certain points have, however, been presented which it was thought should be understood by medical men, and which, it is hoped, may enable them to successfully employ this agent in the treatment of disease; for a thorough knowledge of the matter, the reader is referred to the several valuable works which have been published, among which may be named,—Althaus on Medical Electricity, 1 vol., p. 352; M. A. de la Rive on Electricity in Theory and Practice, translated by Charles Walker, 3 vols., p. 603; *De l'électrization localisée et de*

son application à la physiologie, la pathologie, et la thérapeutique, par M. Duchenne, p. 809; Harry Lobb on Galvanism, p. 152; On Animal Electricity, by E. Dubois Raymond, p. 214; Humphrey's Electro-Physiology of Man, p. 228; and A. C. Garratt's Medical Uses of Electricity, p. 716.

OCCUPATIONS. SOCIETY. PASSIONS. MENTAL INFLUENCES. GENERATIVE FUNCTIONS.

In a state of health, in whatever circumstances of life a man may be placed, his well-being requires the means for exercising his muscles and his mind; a purely sedentary life being a permanent cause of disease and death. Man was never designed by nature to languish in a state of repose, and an effeminate life subjects him to unhealthy humors and diseases; he must not only strengthen the mind, but more especially the muscles in order to render himself healthy, stout, and vigorous. If this be true for persons already in the enjoyment of health, it is much more so, as a general rule, for those suffering from chronic diseases.

However, it is a very frequent occurrence that a patient afflicted with a chronic affection, pursues an occupation quite incompatible with his disease, as well as with its successful treatment, and which he is compelled by the force of circumstances to continue; thus, a mechanic, or a professional man, whose family is dependent upon him for support, and whose pecuniary situation is but moderate, will be required to continue his labors, whatever they may be, until his disease prostrates or destroys him. Sewing females, and sedentary persons generally, are more especially found in this category. With such patients, although circumstances are against them, yet the physician must endeavor to prescribe such a course of hygienic measures as will prove as beneficial for them as the circumstances will allow, and which their conditions will permit them to practice. However, there will be instances frequently presented where a complete change of the business occupation of the patient will be imperatively demanded, in order to preserve life; and great tact and judgment is required on the part of the practitioner in selecting a vocation suitable to the disease and the peculiar circumstances surrounding the patient. A very erroneous idea prevails in society, I may say both among patients and physicians, or, at all events if it is not really entertained, the course pursued certainly favors the belief that it is, and which is, that no matter what may be the nature of a chronic disease, if it does not too greatly debilitate, or, if taken under treatment at an early period, the physician ought to be able to treat it successfully, with-

out regard to the patient's occupation. Such an idea is decidedly wrong, and is fraught with evil to the patient's health and purse, as well as to the physician's professional reputation; and medical men can not be too careful to disabuse the public sentiment regarding this point.

Persons of lymphatic constitution are, as a general rule, unfit for severe daily labor, and should, therefore, endeavor to follow a profession requiring only a moderate degree of exercise, as for instance, gardening, etc., and, on the other hand, they should carefully avoid all occupations of a sedentary nature. Persons predisposed to consumption and to scrofulous diseases, should remove to country places where the climate is equable, and the air is pure; if possible, they should pursue the chase, hunting, horseback riding, agricultural labors; if they are wealthy, the greater part of their early life should be passed in traveling from one healthy position to another; otherwise they should occupy themselves with business which requires traveling, as agents, peddlers, collectors, etc. The vocation of a sailor will be found beneficially adapted to most persons of this kind. Gardening, dumb-bells, jumping the rope, moderately dancing, horseback exercise, and calisthenics, are more especially suitable for females.

The military service is improper for persons disposed to consumption, or born of consumptive parents, because the duties to which the soldiers are subjected, especially those belonging to the infantry, frequently give rise to this disease. The children of consumptive parents, those born in very moist countries or in the neighborhood of swamps, as well as laborers, etiolated by dwelling in cold and unhealthy workshops, should not, as a general rule, be admitted into the ranks of the infantry; the service in the navy is better adapted to them. Agriculturalists, men accustomed to labor in the open air, and mountaineers, form the best soldiers for land service.

All occupations in which the atmosphere is more or less filled with floating particles of dust and various foreign articles, should be avoided by persons disposed to diseases of the eyes, nose, throat, or lungs; too moist an atmosphere, or sudden changes from warm to cold or cold to warm, should especially be avoided by this class of patients, as well as by those subject to diseases of the ear. Persons whose business requires them to travel in railroad cars where there is a constant supply of dust and cinders, should protect their ears therefrom by inserting a small pledget of cotton in each ear; and those who are subject to diseases of the air-passages, should also guard them as much as possible from the action

of the dust, etc. Any profession requiring a constant stooping position is improper for a patient laboring under any chronic disease whatever.

The most suitable occupations for females, as far as regards health, are, sewing with machines, attendance in retail dry-goods or fancy stores, either as proprietresses or clerks, photographing, traveling as agents, railroad conductresses, gardening, calisthenic instructresses, telegraphing, clerking in a post office, and, indeed, any character of business requiring moderate exercise, with more or less exposure to the open air.

Indeed, occupations in which a fair amount of exercise is called for, with opportunities for enjoying the open air, and in which no severe mental labor is required are preferable for all chronic patients, avoiding, as much as possible, sedentary professions, confinement in close rooms, inhalation of an impure or dusty atmosphere, obnoxious vapors, exposure to steam, cold, damp, etc. In the treatment of chronic disease, it will be seldom required of the patient to neglect his business, indeed, it is preferable that he should pursue it, so long as fatigue and exposures are avoided; of course, this does not refer to those patients, the severity, character, or duration of whose diseases has so greatly debilitated them, as to compel them to confinement within doors, nor to those with whom exercise would increase the severity of the disease, or endanger life.

It is of importance that the physician attends to the character of the companions with whom his patient associates; he should be advised to avoid all society of a gloomy, or a too excitable character. Cheerfulness contributes greatly to assist in the restoration to health; hence, the society should be cheerful and pleasing, avoiding those persons who are given to recommending recipes and new cures, finding fault with physicians in attendance, or discouraging the patient by unfavorable predictions, etc. Unfortunately for the sick, there is a class of persons who seem to delight in depreciating the merits of medical men, and who are ever ready with some recipe, of the action of which upon the system, they are wholly ignorant, but which, according to their statements, must be sure to cure, "because Mr. so-and-so, or Mrs. Thingumy," as they have been informed, "had exactly the same disease, and was cured by it, after having tried all the doctors without any benefit." Or, again, "if you keep on with Dr. — you will be sure never to get well, because there was Mr. —, and Mrs. —, and Miss —, who were treated by him, and all of them died." As if medical men possessed omnipotent power to remove disease

and prolong life—and which statements are more commonly either untrue, misrepresented, or exaggerated. Such persons are the patient's bane, more to be dreaded by him than by the physician.

Between the mind and the body there is a direct and intimate sympathy, and so powerful is this, that any disturbance of the one produces a corresponding influence upon the other. How this sympathy of action between the two is effected, is still a matter for philosophy to discover. Yet it is well known that the passions have exerted such an influence upon the system, as to have caused the hair to become suddenly whitened, to have given rise to fever, epilepsy, paralysis, insanity, apoplexy, etc., according to the character of the passion, and the peculiar temperament and predispositions of the constitution. It is not a matter of astonishment to observe the amount of disease and premature death in this country, when we understand the excessive and continued action of the brains of its citizens, in search of pleasure, profit, or discovery. A certain amount of mental exercise is necessary for the health of the body as well as health of the brain; and either an augmented or decreased amount of this action exerts a proportional deleterious influence upon the whole man. The *natural passions* of the human mind, which, when controlled within proper bounds, are intended for salutary and useful purposes, become powerful causes of disease when permitted to be aroused by improper objects, or when allowed to proceed to an unreasonable or ungovernable extent; and these, in particular, should be studied, in order that they may be held subservient to the health and proper comfort of each individual.

The mind of a patient should be kept as calm and regular as possible; and everything calculated to maintain a constant state of despondency, doubts, or anxious thoughts, should be avoided. He should not yield to the influence of any powerful or irregular passion, as joy, grief, jealousy, anger, fear, etc., because an excess of any passion, or a continuation of passions which keep the mind, and through it the body, in a constant state of excitement or depression, always produce unfavorable impressions upon the system, retarding the cure, and not unfrequently aggravating the disease. A moderate degree of those passions which produce pleasant impressions, materially aids in the restoration to health, and patients should be advised to cultivate these passions to a reasonable extent, as a powerful auxiliary to the general therapeutic treatment. A constant state of mental anxiety, or of uncertainty, in relation to any matter, is not only deleterious to health, but has a powerful influence in preventing a recovery from

disease; the physician should endeavor to guard his patient from these influences as much as possible. Mental influence exerts a much greater power over the body for good or evil, than ordinary medicinal treatment; and in the treatment of all diseases the medical attendant should not rely upon his remedies alone, but should cultivate, direct, and, if possible, control the mind of his patient, so as to dispel doubts, anxieties, and despondency, by effecting a state of mental calmness, encouragement, and confidence. I am fully satisfied that there are many patients laboring under severe forms of disease, who can be cured solely through the agency of the mind—an agency but little understood by medical men, and especially by those who imagine that disease can only be removed by drugs, and that a “placebo” treatment is gross deception—the patients of such men are greatly to be pitied.

As for myself, I take the ground, that when a patient applies to a physician he applies with the view of being cured, and cares not what may be the means used, so that they are not of an injurious character—hence, I employ whatever means I believe capable of effecting a cure, without regard to the source from which they are derived—and if I can perform the cure solely through mental influence and placebo remedies, I will not adopt any other course—it is my privilege and right as a physician to do so—and it is a duty which my patient expects and requires of me. His grand object is to be cured—mine, to cure, without a slavish deference to books or authorities. The Almighty has given to every man brains, mind, reasoning powers, judgment, etc., for his own use and to determine his own actions in life; and he, who dare not employ his mind and act for himself, but who tamely yields to the dictates of others, is unfit to be a freeman—is indeed, already the most contemptible of all slaves. Slavery of the body is due to the unjust principle that “might makes right,” and is a forced servitude; but, where the body and mind are both free to act, and the person voluntarily submits to the views and dictates of others, as, observed among the so-called “old-school doctors,” who, as if nature, who in general distributes her gifts with an impartial hand, has favored them with all useful knowledge in matters of medicine, to the exclusion of all others, bow with servile reverence to authority, who dare not employ or investigate outside of their own pale, who persecute all who have the manliness to investigate for themselves, and who discourteously treat all whose opinions differ from their own—such a condition of voluntary slavery is truly most contemptible, and the craven slaves deserve to be both pitied and despised.

While referring to the passions, it may not be amiss to say a few words concerning the function of generation. Excess in sexual indulgences will of itself engender disease among the most healthy persons, producing imperfect nutrition, difficult digestion, emaciation, paleness, sadness, debilitating sweats, difficult breathing, palpitations, aneurisms, pains in the chest, back, shoulders, head, and loins, nervous diseases, epilepsy, paralysis, consumption, dullness and hollowness of the eyes, weakness of sight, vertigo, premature wrinkles, etc. If one wishes to be young in this respect when he becomes old, he must be old while he is young.

When cohabitation is followed by one or more of the following symptoms, as great exhaustion, palpitation of the heart, debility, headache, especially in the back part of the head, dimness of sight, inability to concentrate thought, physical or mental indolence, weakness of the back, transient loss of memory, bleeding from the nose, or nervous irritability, however slight, or of however short duration they may be, it is an indication that the sexual act is carried to too great an excess, even though several hours should elapse before the symptoms manifest themselves; in such cases, the health and life of the person demand that he be more moderate in his pleasures, or abstain from them for a time or altogether. The latter, more especially when, with some of these symptoms, a weakness of the genital organs is experienced.

The man who abuses himself is cacochymied at twenty-five, and old at thirty; the wise man, moderate in his desires and acts, still enjoys the favors of nature at sixty years. For the youth, as well as for the old man, love is a siren, which charms and injures those whom it subjugates; the first has need of all his forces for growth and mental strength; the latter, to preserve his life; the offering which they lay upon the altar of Venus, they have wrested from that of Hygiea, and the result is debility, moral perversion, disease, and death. Age modifies the conditions of all our organs, and as we advance in years we should likewise modify all our habits and desires. The physician should not flatter men of fifty, or women of forty years of age; for at these ages, with a few exceptions, the virile energies commence to diminish, and although in the man, semen continues to be formed in the testes, yet the failure of nervous and muscular power admonish him that nature desires to free him from any further efforts to reproduce his kind.

There is nothing that costs the system so much as the act of reproduction; in transmitting life we transmit even our own. The semen is, as it were, life itself, and is parted with only at the expense of the nervous system and of the vital principle; when

improperly discharged it gives a shock to the organism, which deteriorates the being, by lessening the powers of the mind, debilitating the whole system, and hastening death. If man conformed to the laws of nature, morals, and health, his sexual contacts would be very rare; they would occur solely for the purpose of reproduction, and never out of the sacred ties of wedlock; they would be avoided, with a view to the health of the mother and of the child, both during gestation and during the suckling period, as well as during the most simple indispositions. At the age of sixty, they would be avoided altogether. But, molded by social customs, and deceived by his prejudices and pleasures, man does not perceive the true plan of nature, and abuses that pleasure which should be the most infrequent. And when we consider that men through their perverted imaginations have made a necessity of this excess; when we see sickly beings or those of a delicate constitution giving themselves up to erotic spasms, even to delirium; when we observe aged men, men with white hairs or bald heads, so imprudent as to give themselves to pleasures which nature would have them shun, we may comprehend why there are so many miserable and deformed infants, so many incurable diseases among adults, so many sudden deaths in advanced age. He who is desirous of preserving his intellect and his health, will never be guilty of excess in the generative act, and will cease it altogether at the age of sixty. Those who seek to over excite their worn-out and decrepit organs, by so-called, aphrodisiacs, cantharides, flagellation, and by changing the persons with whom they debauch themselves, are always punished by decrepitude, insanity, and idiotism.

The seminal fluid is the balsam of life; it gives life and preserves it. While its ejection enfeebles, its preservation in the natural reservoirs sustains and increases strength and health. Newton and Pascal were chaste and continent their whole lives. Athletes condemn the sexual organs to inaction. A young man who abstains from the pleasures of love, will be able to apply his mind more intensely to his studies, and will have more agility and strength in his gymnastic exercises; continence will always assure him the victory.

Aside from the fact that a large proportion of chronic diseases among males and females, are due to sexual excesses and abuses, it is an undoubted truth that the incurability of many of these diseases is owing to a similar cause. Physicians prescribe medicines, order diet, exercise, etc., but rarely, if ever, notice the sexual functions, either from a sense of false delicacy, or because an attention

to these functions is not deemed essential in the treatment; and yet there is no portion of the treatment of greater importance to the patient than this, so constantly and universally neglected. A person afflicted with a chronic disease should be prohibited from sexual indulgences, he should be advised to shun all physical and mental excitements, books, tableaux, spectacles, and even companions, which can in any manner excite obscene desires or lead to lewd ideas. He should, in a word, be physically and mentally continent. Sexual feelings irritate the brain and spinal marrow, which irritation is extended over the whole organism, producing more-positive evil upon it, than can be done by a neglect of many important hygienic measures. Let physicians, who have their patient's welfare at heart, bear this in mind; an attention to it will reflect to their professional credit, and will facilitate the patient's restoration to health.

CONSTIPATION. REGULARITY OF BOWELS. ATTENTION TO THE CONDITION OF THE STOMACH. REGULARITY OF THE FUNCTIONS OF THE KIDNEYS. URINE IN HEALTH AND IN DISEASE, AND ITS INDICATIONS.

In the treatment of chronic diseases it is of the utmost importance that the bowels be kept regular daily; a constipated condition augments unfavorable symptoms, prevents the proper action of remedies, and retards recovery. The alvine matters are composed not only of the non-nutritive portions of food, but also of a quantity of humors which, from want of harmony, disagree with the functions and with health.

Liquid and badly elaborated stools are the result of a morbid condition; if they are allowed to continue, they gradually lead to debility, emaciation, and hectic fever.

When the stools are too hard, or of difficult evacuation, the visceral circulation becomes obstructed, from whence results plethora, cerebral congestions, etc.

However, nothing is absolute in the organism taken in its totality; nothing is exactly alike among individuals. Some appear to be naturally disposed to costiveness, while others have their stools quite soft, and, in either case, without affecting the health; the former owe their constipation, in a measure, to the energy and the dryness of the intestinal tube; the latter to a state of relaxation and to the more ready secretion of intestinal mucus. Rare exceptions have been met with in which persons could remain for a long time without defecation, and without any appreciable injury to health; and old men are sometimes known to have enjoyed the best health only when they were slightly constipated. But, al-

though this may be true in a state of health, in the treatment of disease a different order of things must be observed.

As a general rule, well-formed dejections, somewhat soft or a little hard, not of too dark or too light a color, exhaling but little odor, and occurring at regular periods once in every twenty-four hours, indicate that the digestion is complete, that it is finished, that it is restorative, that the digestive tube is in a good condition, and that nutrition has been well made.

With but very few exceptions, in the treatment of chronic diseases, it is an imperative duty of the physician to make use of means to regulate the bowels of his patient, so that he will have one healthy natural evacuation, at regular intervals, in every twenty-four hours, and never to exceed two, as in the case of some plethoric or corpulent individuals. Without an attention to this matter, but little benefit can be expected from treatment.

Active purgation does not remedy a torpid condition of the bowels, and is very seldom required in the treatment of chronic diseases, except at the commencement of the treatment, to remove accumulated feculent matter, in cases where there has been an obstinate constipation for some time previously, and in some few cases where the derivative influence of catharsis is required. More injury has been effected by active purgation than by any other kind of medication, especially since the introduction of Le Roy's purgative, Hygiene pills, Brandreth pills, and a host of similar nostrums: diseases of the eyes, inflammations and irritations of the digestive tube, torpid liver, hemorrhoids, enfeeblement of the peristaltic nervous power, incurable constipation, and many other difficulties of the abdominal viscera, have been the results of the continued employment of these drastics. Purgatives reduce the temperature, remove morbid products, act as derivatives, and aid in the elimination of urea, and are, generally, more useful in the early stages of active diseases; in chronic diseases they are rarely indicated.

If possible, the bowels should be regulated by articles of food which agree with the stomach, and which do not neutralize or interfere with the action of the medicines prescribed, as, ripe fruits, stewed fruits, dates, prunes, figs, brown bread, Indian-meal, corn bread, etc. If these do not answer, daily injections should be employed whenever they will answer the purpose. The injections may consist merely of cold water, or cold infusion of bitter tonics, and where there is a great loss of nervous energy, some Tincture of Nux Vomica, or Solution of Strychnia may be added; these will be found, in every respect, superior to injections composed of laxative

medicines, a continued use of which will give rise to debility of the intestines and augment the difficulty which we are endeavoring to obviate. In order to suit the convenience of patients, who object to injections during the day, the best time to administer them, is immediately after rising in the morning.

Many patients have a great aversion to the use of injections; in such cases, as well as in those where the other means heretofore named fail to effect the desired result, it will be necessary to have recourse to laxatives, as will be found under the treatment for constipation, of which I employ the powdered Rhubarb more commonly.

In all cases of costiveness every proper means should be employed to establish a healthy regular action of the bowels, and when this is once established, the agents employed for this purpose should be omitted, not suddenly, but in a gradual manner. An attention to the preceding hygienic measures is of such great importance to the patient that I am thoroughly convinced, from experience, that at least one-half of the chronic diseases to which mankind are subject may be permanently cured by a rigid attention to them, especially to those which relate to the skin, the bowels, exercise in the open air, and diet, and this, too, without a particle of medicine being used.

While on this subject, I will make a few brief statements relative to the condition of the stomach, which may prove useful to practitioners engaged in the treatment of chronic diseases. I have found in my practice that the state of the stomach has much to do with the action of remedies taken into it; thus, when there has been an acid condition of the stomach, known by the white coat on the tongue, the agents which have been successfully prescribed in other cases of disease, similar to the one under consideration, have often failed to produce any beneficial results; but, as soon as the acid condition was removed, the remedial influence of the agents were immediately appreciated. This condition of the stomach is frequently a great obstacle to the action of medicines, and thereby to the patient's recovery, and physicians should constantly bear it in mind. I have frequently treated cases who had been under the previous attendance of medical men without deriving any benefit whatever, and have cured them by the administration of the same remedies that were prescribed for them by the former medical attendant, solely, by first removing the acid condition of the stomach, which had been neglected or overlooked, and which acidity interfered with the medicines, either by changing their character, neutralizing their effects, or by impairing the sensibility

or impressibility of the vital powers of the stomach. A debilitated condition of the stomach, known by paleness of the body of the tongue, or an irritated or inflamed condition, known by unnatural redness of the body of the tongue, will frequently produce similar results, the medicines administered not acting favorably until the abnormal condition has been modified or removed by appropriate treatment. May not this be one of the reasons why there is such a discrepancy in the views of medical men regarding the therapeutical influence of certain valuable medicines; some of whom consider them of great efficacy, while others deny that they possess any remedial virtue?

An attention to the action of the *kidneys* is likewise an all-important measure in the management of chronic diseases; as these organs remove from the blood all those effete matters which, if permitted to remain, would speedily destroy life. The quantity, quality, odor, and color of the urine are so many indices, diagnosing the character of many diseases, as well as prognosing their progress. A medical writer makes the following remarks relative to the urine:—

“In times past, the physical qualities of the urine, that is, its color, odor, deposits, more or less critical aspects, etc., were only considered in the diagnosis of disease, giving, indeed, but an imperfect idea of its nature or treatment. But, in modern times, chemical analysis and the microscope have shed the most important light upon disease and its treatment. The fathers of chemical science, Lavoisier, Fourcroy, Vauquelin, and others, decomposed the urine, demonstrated it to contain the elements of stone, gout, scrofula, dropsy, hepatitis, etc., explained a host of vital phenomena until then enigmatical, and gave some hope of being able to discover the source of diseases, and of verifying certainty in their treatment. Soon after, Becquerel, Lecanu, Nauche, Rayer, etc., indicated the existence of several diseases by an examination of the urine, as, diabetes, dropsy, diseases of the kidneys and of the bladder, and even the condition of pregnancy at its very commencement. Andral and Gavarret also, attending to the microscopic investigation of the blood, observed inflammation, chlorosis, syphilis, and scrofula, in the alteration of the globules of the blood, and in the proportion of its fibrin. Lauwenhoeth, Kerschen, and other micrographers, detected in animal fluids myriads of moving bodies, (*animalcules* ?) whose forms varied according to the medium they inhabited; circulating with the blood, chyle, milk, serum, saliva, swimming in ichorous fluids, or in purulent matters,

they escaped with the urine, astonishing these observers by their number, forms, and exceeding tenuity.

“At this day, the micro-chemical investigation of the urine, notwithstanding the aversion or distaste of such study, is pursued by all true and sincere physicians who desire to benefit suffering humanity. It has already revealed the existence of many serious diseases, even before our other modes of investigation had been able to indicate them, and has thrown light upon a host of chronic diseases, the cause, progress, and treatment of which was unknown or involved in much obscurity.

“The urine comes from the blood, and serves to purify it; being separated from it by the kidneys, which are the secretory organs of the urine, from which it is conveyed to the bladder for expulsion, by means of the two tubes called ‘ureters.’ All the morbid principles which alter the blood and injure health appear to enter into its composition; thus, it is found to contain bile, milk, blood, fat, pus, urea, gelatine, albumen, tuberculous matters, as well as microscopic vegetations and animalcules; it also contains the chlorides, phosphates, oxalates, and sulphates of lime, ammonia, etc.; likewise most of the medicines as well as the poisons received into the system; it also contains the elements emanating from diseased organs, in most, if not in all instances. It varies according to the health, gives the premonitory indications of disease, pointing out its increase or diminution, the danger or return to health; it removes from the system pernicious and hurtful humors, as well as the used-up or effete matters thrown off from our several organs.

“When passed shortly after drinking, or after a meal, the urine is not yet perfected, it does not contain the salts, the principles of disease, nor the organic elements which enter into its composition when passed at a later period; it is only the urine from the drinks taken. But the urine passed on rising in the morning, several hours after a meal, and which has been elaborated during sleep, is the urine from the blood, and contains all the properties of urine, all the elements or principles of disease; and is that which the physician should prefer for analysis. For the medical man, it is the compass which guides him in the unlimited chaos of disease and in its treatment; for the patient, it is the thermometer of his condition, the premonitory indication of the decrease or aggravation of his malady; and for the healthy man, it is the regulator of his diet and of his life.

“No fluid of the economy is more rapidly modified by diet, temperature, change of habits, or moral impressions than the

urine; thus, it becomes fetid by the use of asparagus; acquires the odor of violets under the influence of turpentine, resins, and some volatile oils; it becomes red by the use of sorrel, the root of the strawberry plant, red beet or madder; black or dark by the employment of cassia, or the preparations of iron; while fear, grief, anger, and all lively impressions suppress it, or cause it to flow more limpid and more abundantly.

"During health, the quantity of urine is nearly one-third or one-half of that of the food taken; women furnish more than men, and children more than adults; vegetable diet renders it more abundant than animal, and it is also secreted more abundantly during the night than through the day. As a general rule, the secretion of urine is in inverse ratio with the other secretions, as, the saliva, perspiration, and stools; its temperature is always equal to that of the body, and is nearly the same with all persons.

"Slightly odorous and slightly colored in the earlier years of life, the urine contains but little except some phosphates and benzoic acid in small quantity, among healthy new-born infants; phosphate of lime and phosphoric acid develop themselves in greater abundance as we advance in years; and it is the presence of these salts which dispose old men to calculi and diseases of the urinary passages.

"The morning urine, when in a normal condition, is transparent and of a lemon-yellow color, of a uniform tint, and more deeply colored among men than among women and children; it is higher colored among those of bilious temperament, shaded only by a light cloud, which is conveyed to the surface of the fluid, and which soon contracts, condenses, falls, and is deposited as a white sediment, leaving the urine perfectly clear. And if this urine is never too highly colored, nor too much loaded with salts, etc., if its amount is proportioned to that of the drinks, if the elements constituting it are in just proportion, it indicates vigor, and a good condition of the organs. Similar urine voided in the morning after the night's rest, without any effort, and in proper quantity, is an indication of good health; it shows that the habits of living are regular, that the excesses of the previous day have not surcharged the stomach, nor enfeebled the organism; it also shows that the function of digestion is accomplished without effort or difficulty, that the night's sleep has proven restorative, that the mass of blood is of a good character, and that the functions are well performed.

"But any change in the urine is a change in the economy; thus, the urine is always less abundant and higher colored previous to

acute and painful diseases; in the commencement of eoryza and rheumatism, it is in small quantity; it is scanty after violent exercise, perspiration, and serious diarrhea; at the onset of most inflammatory diseases it is higher colored and in diminished amount; and if it continues scanty throughout the course of the inflammation, especially when this is located in the lungs, and albumen is also formed in it, the prognosis is unfavorable, and both patient and physician must be on their guard.

“When the urine is too abundant, it indicates a general debility, or relaxation and alteration of the kidneys; this abundant flow apprises hypochondriacs and hysterical persons of the approach of their crises, and when the abundance continues for a length of time, emaciation is present. This abundance is an unfavorable indication in chronic diseases; it is indicative of the obstinacy of the congestions, but it does not indicate diabetes mellitus, unless analysis discovers in it saccharine matter, lactic acid, lactate of ammonia, albumen, and the other principles common to it in this disease.

“Turbid urine may be the result of colds, of too violent exercise, of any excess at the table, or of some lively moral affection; it is also the forerunner of rheumatism, gouty affections, catarrhs, or the secret progress of a chronic disease. This turbidness is due to a defect in the proportion of the constituent elements of the urine, there being an excess of gelatinous animal matter, uric acid, and urate of ammonia.

“If the turbidness of the urine is persistent, if it contains flakes which float in the fluid and are not precipitated, if it is a little darker colored, if it imparts a yellow stain to white linen, if there becomes attached to the sides and bottom of the vessel containing it, a yellowish, reddish, or brownish substance, loaded with small crystals of phosphoric and uric acids, if it contains albumen, these are serious indications in acute diseases, announcing obstinate engorgements of the abdominal organs.

“Every one is aware of the variations of the barometer, and we know that the fluctuations of the column of mercury are closely associated with the variable conditions of the atmosphere; so, to the practised observer, variations of the urine as well as of the elements composing it, point out with certainty the changes in health, and the condition of organs. Is the urine mucilaginous, viscid, albuminous and frothy, the disease is of a consumptive nature, and the patient wastes away; and if this appearance of the urine is persistent, if whitish granulations united in groups in an obscure and cloudy mucus are visible under the microscope,

(or pus globules), pulmonary consumption is imminent. At a later period, if these granulations increase, becoming larger and forming granular globules, the urine being more alkaline, it is an indication of the advanced progress of the consumption. Finally, if these granulations dissolve and become transformed into a filamentous matter presenting opaline spots, the urine being more alkaline and containing more albumen and more of the ammoniaco-magnesian phosphate, the consumption is 'galloping.'

"Take urine apparently normal, indicating health, place a drop or two under the microscope—if grayish globules, more or less voluminous, are observed, in masses, suspended in a mucus *sui generis*, it is indicative of cancer. If these globules are brownish, the mucus whitish, the transparency of the urine disturbed, the urine less acid, more alkaline, and more albuminous, it is cancer of the womb. The quantity, the color, and the nature of these elements are the sign, the measure, and the degree of the disease.

"A pale and slightly greenish urine, indicates discoloration, anemia, chlorosis, debility; if this urine becomes mucus, more dense, more acid, precipitating, upon the addition of nitric acid, an abundance of urates, if it contains albumen, it indicates a disease of the heart.

"An orange-yellow urine indicates a commencing inflammation; more deeply colored, saffron or brownish, the skin being yellow, jaundice is present; still more deeply colored, inclining toward a brown, staining linen of a very bright color, containing more uric acid and more albumen, the liver will be found engorged; serious disease is manifesting itself. Finally, if the urine is of saffron yellow color, dense, and of the consistence of thin starch or wet clay, containing, moreover, albumen and purulent matter, it signifies a serious disorganization of the liver, or an abscess of this organ.

"At the commencement of an attack of gout, little or none of the acid phosphate of lime is present in the urine; at the termination of the attack the phosphate reappears, and the urine returns to its normal condition several days after the cessation of the inflammation, always holding minute grains of crystallized uric acid in suspension.

"In diabetes, the urine contains little or no urea, a saccharine matter, albumen, etc.; the urea reappears, and the albumen and saccharine matter disappear only with the return of health.

"A child is attacked with cough and soreness or inflammation of the throat or air-passages; if its urine is white and turbid, milky, more scanty than in the normal state, disengaging carbonate of ammonia, it warns us of the presence of croup.

“When the urine is loaded with phosphate and carbonate of lime, it indicates softening and deformation of the bones—it is the work of dissolution of the bony system, rickets; the calcareous phosphate of the bone is absorbed and carried off, while the gelatinous or animal portion alone remains. This softening, ulceration, dissolving, or serofulous condition of the bones, appears to be the result of a strumous principle combined with a peculiar acid, which is always met with in the urine of these unfortunate patients.

“If the urine is bloody, it may be due to disease of the bladder, of the neck of the bladder, of the ureters, or of the kidneys; or there may be calculi in these organs lacerating them; or, it may follow the rupture of some blood-vessels consequent upon a fall, blow, or strain.

“If the urine is purulent, the pus comes either from the altered and diseased bladder, prostate, neck of the bladder, or kidneys; or it emanates from other organs laboring under far advanced organic lesions.

“An albuminous, purulent, and bloody urine indicates a cancerous disorganization of the urinary passages. If it contains organic detritus, decomposed blood, and albumen, it points to an alteration of the kidneys, to Bright’s disease. Is the urine purulent, albuminous, and sandy or gravelly, there is renal calculus, with abscess of the kidneys. Is it only purulent, the pus comes either from the bladder, the neck of the bladder, prostate, or the kidneys; or it emanates from other organs suffering from advanced organic lesions. It is in this kind of urine, and from the nature of the elements it contains, that the physician, armed with the microscope and chemical analysis, will be enabled to recognize the hidden cause of disease and of the alteration of organs, and, by this kind of investigation, to discover the remedy and often effect astonishing cures.

“When the urine is less abundant, albuminous, with diminished urea, dropsy is making its appearance; but if, at a later period, it becomes red and turbid, depositing an abundant flocculent sediment, sometimes reddish, at others whitish, giving a strongly ammoniacal odor, readily frothing upon agitation and remaining so for some time, also giving by analysis, ammonia, sulphates and phosphates of lime, albumen, a coloring oily matter, morbid elements, little or no urea, it indicates a rapidly fatal dropsy.

“In all diseases, if the urine continues dense without any deposit, having the color and consistence of oil, containing albumen, and having a fatty pellicle floating upon it, it indicates marasmus,

decomposition ; and if to these qualities is added a deep red, brown, or blackish color, the prognosis is fatal.

“ But, if a cloud forms in the urine, condenses, and falls down, if the morbid elements diminish, the prognosis is more favorable, and the disease will be of shorter duration. Fortunate is that patient whose urine gives a cloud which condenses, falls, and forms a deposit ; but we must suspect urine which, at the commencement of disease gives signs of coction ; still more must we distrust urine in which the cloud formed, instead of being deposited, is elevated and kept at the surface.

“ Urinary deposits are according to the disease ; being sandy and gravelly in gravel, stone, and congestion of the abdominal organs ; often tinged with blood in diseases of the kidneys, ureters, and bladder ; purulent in ulcerations of the urinary passages ; red, and like brickdust in rheumatism and anasarca ; reddish and in abundance in coryza and pulmonary catarrh ; whitish, and attaching themselves to the sides of the vessels holding the urine, in all diseases where there is debility and relaxation of the mucous membranes, as in chronic catarrh, piles, and where there is a tendency to dropsy. In abdominal congestions, hypochondria, chlorosis, and intermittent fevers, these deposits frequently have the appearance of bran or meal ; in softening of the bones they are loaded with phosphate of lime ; in diseases of the liver they are of a saffron-yellow color ; and in croup they are white and milky, becoming blackish in the most dangerous cases.

“ These are a few of the facts connected with the examination of the urine in disease. To give, even summarily, the innumerable shades of this fluid in diseases would not only require a large volume, but the aid of the painter would be necessary ; and to describe the numerous elements which compose it, in health and disease, would require a treatise on organic chemistry. We would have to refer to ancient and modern examinations of the urine ; to reproduce the analysis of Chaptal, Fourcroy, Le Canu, Becquerel, Vogel, Neubauer, Funke, Verdeil, Beale, Bird, Hassall, Thudicum, and others, with the urine of rickets, gout, dropsies, syphilis, fevers, stone, etc., as well as the observations of micrographers upon the blood, pus, semen, and animalcules contained in the urine ; we would have to show the alteration of the blood when it has reached the kidneys, as well as the other viscera, giving its normal and abnormal elements which escape through the urine ; to show that the presence of albumen, in nearly all chronic diseases, from simple gastralgia even to diseases of the brain and spinal marrow, indicates the tendency to dropsy, and even to that grave and hopeless mal-

ady, albuminaria; and to form a treatise upon organic chemistry and microscopic observations."

Although I am not prepared to indorse all the statements of the above writer, yet he has referred to a sufficient number of facts to point out to us the imperative necessity of attending to the urine, both in health and in disease, and of maintaining the kidneys and urinary apparatus in as normal a condition as possible, for any departure from this exerts a proportionate deleterious influence upon the organism.

In order that the practitioner may understand some of the conditions of the urine in health and in disease, I will give a brief statement compiled from the best authorities; remarking that the nearer to a normal state the urine is maintained, the nearer is the approach to health,—and if a patient finds his urine gradually becoming more natural, as regards quantity, quality, color, odor, and deposits, he may rest assured that disease is gradually being removed to make way for a state of health and strength. I will also observe, that in prescribing constitutional remedies to patients, I always watch their influence upon the urine, and if I find a particular one affects this fluid so as to cause a more healthy condition of it, I persevere in the use of such particular article or articles as long as this influence continues, having found from a long experience that those particular alterative or constitutional remedies are the best and most suitable to the individual cases in which they are given, that gradually correct the color, quantity, and quality of the urine; indeed, as a general rule, they are the remedies with which to perform a cure in such individual cases, if a cure is at all to be had.*

*There is a class of men who style themselves "uroscopians," or "urine doctors," and who pretend to diagnose diseases and prescribe to patients from a bare inspection of their urine; and although it has been frequently demonstrated that not one of them can distinguish the urine of a horse or of any other animal, from that of a man, yet it is strange what unlimited faith the common people have in their skill; it is very rarely indeed that these men effect cures. To show that their diagnosing by the urine is simply an imposition, or a system of guess-work, I give what was sold to a young man for an extravagant price as "*Dr. Dellembaugh's mode of discriminating diseases by the urine,*" as follows:

"*Dropsy.* Urine with sediment and beads around the sides of the glass. Test: sulphuric acid will cause the sediment to fall to the bottom of the glass, and remain high-colored.

"*Pains.* When the urine has specks, or an appearance of sand in it, and will not settle.

"*Fever and Ague.* The urine is high-colored at the top, and clear at the bottom, with large beads around the glass.

"*Pregnancy.* Urine has a sediment at the bottom, resembling a bee-hive flattening.

"*Derangement of Mind.* Urine high-colored with large beads on the top,—when

The urine of a healthy individual is, when just passed, clear, of a straw or light amber-yellow color, has the temperature of the body, varying from 92° to 100° F., a peculiar, aromatic, violet-like odor, termed "urinous," a bitterish, saline, somewhat disagreeable taste, and a specific gravity ranging from 1.003 to 1.030, but averaging from 1.015 to 1.0120. That which is passed after drinking much fluid is called *urina potus*; it is commonly pale, and of a specific gravity ranging from 1.003 to 1.009. That which is passed after the digestion of a full meal, is called *urina chyli*, and has a specific gravity of from 1.025 to 1.030. That which is passed after a night's rest, *urina sanguinis*, furnishes the best specimen of the average density of the whole urine, as well as of its normal or abnormal condition; its density is from 1.015 to 1.025. Infants' urine is inodorous, colorless, of low specific gravity, and has but little reaction on litmus paper.

In the examination of urine, the different specimens passed at various periods of the day, should be tested both separately and combined; their color, opacity, transparency, odor, reaction, etc., should be carefully noted. And not only should the urine be

they are around on the sides of the glass, fever is indicated; but when on the top and not around the glass, it indicates more serious derangement of the mind. — Urine milky-white, and producing no stain, indicates lowness of mind, weakness of constitution, nervousness, etc., with other diseases, owing to the age and sex.

"*Worms.* Urine rough and pale, white with slimy sediment.

"*Constipation.* Urine oily on the top.

"*Typhus Fever.* Urine of a dead red color, and the sediment sinks, with no beads or any smell.

"*Common Fever.* Urine shows beads with high bright red color; * if there is much sediment it is a favorable sign.

"*Inflammation.* Urine dark or nearly black.

"*Jaundice.* Urine has a yellowish tinge, much resembling the tincture of saffron; if thick, and a darkish yellow is at the sides of the glass, it is a good sign.

"*Asthma.* Urine light-colored with little sediment and a few beads, but appears to be dusty.

"*Insanity.* Urine milky-white; when sulphuric acid is added it should foam up and turn brown.

"*Diabetes.* Urine of a clear spring color, and sweetish taste.

"*Flooding.* Urine has streaks of blood through it.

"*Rickets.* Urine of a bluish pale color.

"*Tape-worm.* Urine is of the color of that which indicates worms. It can be told better by the appetite. If the patient takes sweet oil for two evenings in succession, he will become very sick and restless.

"*Gravel.* Urine scanty, with lumps of sand in the bottom of the glass.

"*Cow's Urine.* Urine color of water, and smells much of the animal.

"*Beasts' Urine.* Precipitates a sediment when sulphuric acid is added to it.

"N. B. Urine from different persons will not unite."

examined immediately after it has been voided, but also after it has been allowed to stand for twelve and twenty-four hours.

According to calculations made by careful observers the minimum quantity of urine passed by a person in health in twenty-four hours is about thirty-two fluidounces; the maximum amount is eighty-one fluidounces; and the medium quantity is about fifty-two fluidounces. It must be recollected, however, that the quantity of urine passed in twenty-four hours depends upon several circumstances; thus, an abstinence from drink diminishes the urinary secretion, while the injection of large quantities of fluids may increase it even to several pints. Again, when other organs which eliminate water, as the skin, lungs, and bowels are actively engaged in this secretion, the amount of fluid from the kidneys will depend in a measure upon the relative excretory activity of these organs. The quantity of urine is also determined by exercise, rest, sleep, mental influences, atmospheric influences, etc., all of which must be taken into consideration when any great departure from the usual quantity is observed; exercise and the waking condition, as well as certain articles of diet, augment the excretory action of the kidneys, while rest, inactivity, and sleep diminish it, as well as congestion and inflammation of the kidneys, structural diseases of these organs, and acute diseases generally. No conclusion should be formed from the quantity of urine passed in one day; but it should be *measured* for several days in succession.

The maximum, minimum, and mean amounts of the fluids, solids, and various ingredients of normal urine passed during twenty-four hours, as herein given, have been determined by trials on many persons in health by various physiologists,—the persons living well and taking regular exercise. The average of eight or ten days usually gives the proper amount, of the various ingredients, to the individual. If the living, physiological conditions, atmosphere, etc., are kept even, the results will always be about the same with the same individual; any great departure from them, either way, showing a pathological condition.

A person, in the absence of any powerful physiological condition of the skin or body, as when too much or too little fluid is taken, etc., passes about the same amount of urine every day; if he passes an amount which is greatly above or below the limits of the range, proper to him, some pathological cause is generally present. (Parkes.)

According to Vogel and others the following statements deduced from general experience may ordinarily be regarded as facts:

1. The quantity of urine is diminished in all acute febrile and

inflammatory diseases. A constant diminution of the quantity of urine, in most diseases, is accompanied by, and therefore pathognomonic of, a constant increase of the intensity of the disease. When the quantity of urine remains very low ($25\frac{3}{4}$ fluidounces per day), for any length of time, then we may conclude that the intensity of the disease has not abated. On the other hand, a constant increase in the quantity of the urine is a favorable symptom, and shows that the patient has passed the acme, and that the diseased action is abating.

2. When a disease, acute or chronic, takes a fatal turn, the quantity of urine becomes frequently very low, or remains in a fluctuating state; this is not usual, however, in cases where the cause of the fatal termination is a sudden interference with the nervous powers, or with the mechanical action of the lungs and heart.

3. In dropsical diseases, with or without diseased kidneys, the quantity of urine is materially diminished; an increased flow is an indication of improvement, that is when the kidneys are not diseased, as well as an indication for the administration of diuretics.

4. In those diseases termed diabetes, the quantity of the urine is materially increased.

5. During the period of convalescence from febrile or inflammatory diseases, the quantity of urine becomes normal, or exceeds in some cases the normal quantity.

Urine remaining clear and transparent for a short time after being passed, other things being equal, is, in general, an indication of health; yet, clearness alone is not a positive sign, as many abnormal substances and many pathological alterations in the quantities of the urinary normal ingredients may be found in clear urine. If urine is voided in a turbid state, or becomes turbid soon after its emission, with a deposit formed upon the sides and bottom of the vessel containing it, it is an indication of disease, and should be attended to.

The color of urine varies with its quantity and density; that which is passed soon after drinking freely of water or watery fluids is of a very pale straw color, varying from nearly colorless, through a faint greenish tint, up to straw-yellow. It is usually neutral in its reaction, sometimes alkaline, and seldom acid. Persons in an anemic state, whose urine is deficient in urea and solids generally, as well as diabetic patients, are apt to excrete a pale urine. The ordinary urine of health is of an amber color; in hot weather and after active exercise the urine is generally of a dark amber, or reddish tint. Many useful indications relative to the state of the

system may be had by an attention to the color of the urine, the principal of which are as follows:

1. As long as a patient secretes *pale urine*, he is not affected by any severe illness of a febrile and acute nature; he may be anemic or be laboring under diabetes, or some structural disease of the kidneys.

2. Highly-colored urine varies from a *reddish-yellow* to a *red color*, it is of decidedly acid reaction, of high specific gravity, and indicates the presence of a large amount of solids, particularly urea. It may be produced by the persons voiding it drinking only a small amount of fluid; by an excess of nutritive nitrogenous matter in the blood, as, among those who are fond of wines and high living; by violent exercise and free perspiration, which lessens the quantity of water in the blood; and by acute febrile diseases in which there is a rapid disintegration of tissue and waste of matter. Two or more of the above circumstances combined, will also give rise to high color of the urine, as, fever and perspiration, or large meals and violent exercise. The indication, however, from this kind of urine is not to be derived from the amount of fluid passed in a given time, but to the actual quantity of solids this urine contains. Highly-colored urine contains a large amount of uræmatine or coloring matter of urine.

3. Urine colored from *red* to *brown*, or *deep brown*, is generally due to the presence of coloring principles of certain articles, which have been absorbed into the blood, and afterwards eliminated by urine; as, the coloring principle of a strong infusion of roasted coffee, chimaphila, logwood, rhubarb, senna, etc. If a small quantity of mineral acid be added to urine colored by any of these substances, it will change the color to a bright yellow; but if the presence of uræmatine has given rise to the red or brown color of the urine, it will, if changed at all by the acids, become darker. Again, if aqua ammonia be added to urine colored *dark-orange* by rhubarb, it changes the color to a crimson, thus showing it not to be bilious urine, which is of a brown, yellowish, or reddish-brown color, and indicates an impediment to or suspension of the flow of bile from the liver into the intestinal canal.

4. A *red, rosy*, or *pink* color of the urine, or of its deposits, the urine being of an acid reaction, is due to a pathological product termed "purpurine" or "urerythrine," and is indicative of the presence of a very serious pathological condition. It is present in organic disease of the liver, hepatic (not peritoneal), ascites, in splenic diseases, etc., and is indicative of a quickened metamorphosis of hæmatin.

5. The color of urine, varying from *red* to *purple* may be due to the presence of "urrrhodine" or "indigo red," which is a product of decomposition of uroxanthine, and which with blue pigments makes the urine violet. Unless in large quantity, it is not to be considered as a pathological phenomenon, as the health does not appear to be disturbed by its presence.

6. *Lemon-yellow* colored urine is due to the presence of an excess of "uroxanthine" or "indican," with deficiency of uræmatine, and is indicative of diseases of the serous membranes, the kidneys, and the spinal marrow, and cholera. Excess of uroxanthine is apt to be present in diseases of the nervous tissue, phthisis, diabetes, gout, dysentery, reactive stage of cholera, lead colic, Bright's disease, and in chronic atonic diseases, indicating deficient oxidation, and lessened metamorphosis of hematin, or a slightly perverted metamorphosis.

7. A *deep blue* color of the urine may be due to "cyanurine," or "uroglaucine," (indigo), which is sometimes the product of the decomposition of uroxanthine in the ammoniacal decomposition of the urine in the bladder, and has been observed in cystitis and Bright's disease. Cyanurine is a mixture of uroglaucine and urrrhodine.

8. *Yellowish-green*, or *brownish-green* urine is owing to the presence of coloring principles of bile, the urine giving a very acid reaction; it indicates some obstruction to the passage of bile from the liver and gall bladder into the intestines; the presence of the constituents of bile in the blood; or excessive activity of the liver.

9. A *greenish*, *apple-green*, or *grass-green* colored urine is due to a mixture of uroxanthine with uroglaucine or any of the blue coloring principles, the urine being alkaline, decomposed, and containing much carbonate of ammonia; it has occurred in cystitis and Bright's disease.

10. *Violet* colored urine is due to a mixture of the normal red coloring matter of urine, uræmatine, with the abnormal blue pigment, uroglaucine.

11. Dark urine of a *reddish-brown*, *brown*, or *porter-like color*, sometimes like ink, is due to "hæmatin" or dissolved blood corpuscles, which is the result of severe pathological action in the body, and indicates a rapid disintegration of the red-blood corpuscles, as in typhus, inhalation of arseniuretted hydrogen, but which, however, admits of a favorable prognosis, unless it be a symptom of severe scorbutic or septic disorders, or when followed by discoloration of the skin and suppression of urine, in which case the prognosis is very unfavorable.

12. *Black, or blackish-gray urine*, may like the preceding be due to "hæmatin," or to a black pigment, "melanin." But it must be recollected that the urine also becomes black from the internal use of some medicines, as tar, creosote, and carbolic acid.—Hæmatin or blood pigment in the urine gives a more or less brown or black color to it; and indicates a general or local affection of the blood, due to septic or profound cachectic diseases; as typhus, malignant small-pox, pernicious remittents, scurvy, and sometimes Bright's disease, febrile jaundice, etc.

The odor of healthy urine is peculiar, and is incapable of being destroyed by any of the chemical processes used in analysis of this fluid; this normal odor is retained for a long time if the urine be acid, but it soon becomes offensive, if the liquid be alkaline, from decomposition; sometimes it has an offensive odor when first passed, which is an indication of its alkalinity. In acute disease the urine has a strong odor; in anemic conditions its smell is very slight or entirely wanting; in diabetes it has an odor like that of whey, which changes to an alcoholic one when fermentation commences; and it emits a peculiar and fishy smell in some cases of indigestion. An alteration in its odor is occasioned by certain articles of food, as asparagus, beans, onions, garlic, etc.; and some medicines likewise affect its odor, as saffron, eubebæ, copaiba, assafoetida; certain essential oils, etc.; oil of turpentine communicates a violet odor to it.

The taste of the urine is of no scientific value, farther than to ascertain its sweetness in diabetes, which may be determined, however, by other and less repugnant measures.

Healthy urine has an acid chemical reaction, coloring blue litmus paper red. When it has a neutral or alkaline reaction, it is indicative of abnormal action in the system; though an acid urine is not always a sign of health. When neutral, urine has no action on blue or reddened litmus paper; when alkaline it restores reddened litmus to its original blue.

The acidity of the urine is principally due to the presence of acid salts, as phosphates, sulphates, urates, hippurates, volatile odorous acids, as well as free organic acids; a little carbonic acid is also present. This acidity is essential to the urine, as it not only tends to keep the earthy phosphates in solution, but prevents the urine from decomposing too rapidly, and becoming alkaline. Ordinarily, urine upon standing for a time, in hot weather, loses its acidity gradually, becomes neutral, and in two or three days is more or less alkaline. When the urine is preternaturally acid, it

is indicative of acid stomach, derangements of the functions of digestion, gout, rheumatism, etc.

The quantity of the free acid in urine is determined by a very simple volumetric analysis;* it is diminished by the administration of caustic alkalis as well as their carbonates, while it is increased by the use of mineral acids, some organic acids, and some drugs. With some exceptions, the acidity of the urine diminishes in both chronic and acute diseases.

When an acid urine is converted into alkaline within twenty-four hours after it has been voided, it is due to some existing pathological condition. Though it must be recollected that the process of decomposition and consequent alkalinity of normal urine may be facilitated by high temperature, heat, the presence of pus

*The amount of the acidity of the urine is determined by careful neutralizing with soda, and may be expressed by saying, (not that it is equal to so much alkali, but) that it is equal to so much crystallized oxalic acid.

A solution of caustic soda is to be so graduated that every cubic centimeter, (equal to 15.434 Troy grains of distilled water), indicates exactly ten milligrammes (equal to .15434 Tr. grs.), of oxalic acid. For this purpose, one gramme (15.434 Tr. grs.) of dry oxalic acid is dissolved in enough distilled water to make exactly 100 cubic centimetres (1543.4023 Tr. grs.) of solution. Every 10 cub. cent. (154.34023 Tr. grs.) of this solution contains one-tenth gramme (1.5434 Tr. grs.) of oxalic acid.

Ten cub. cent. of this solution of oxalic acid is placed into a small beaker glass, and a few drops of tincture of litmus carefully added to it, until it is colored red. The dilute solution of caustic soda is now to be cautiously added until the red color has been changed into the original litmus blue. Suppose to effect this it requires 6 cub. cent. (92.604 Tr. grs. dist. water) of the solution of caustic soda, then they would correspond to one decigramme (1.5434 Tr. grs.) of oxalic acid.

We now add to every 600 cub. cent. (9260.4138 Tr. grs.) of the solution of caustic soda 400 cub. cent. (6173.6092 Tr. grs.) of distilled water, and thus obtain 1000 cub. cent. (15434.023 Tr. grs.) of standard solution, of which one cub. cent. (15.434 Tr. grs.) exactly neutralizes ten milligrammes (.15434 Tr. grs.) of oxalic acid. If after the addition of ten cub. cent. of this solution to ten cub. cent. of the solution of oxalic acid reddened by litmus, the blue color appears, the solution is correct and ready for use.

To apply this to urine, take 50 or 100 cub. cent. (771.701 or 1543.4023 Tr. grs.) of fresh urine, and add to it in small quantities at a time, not to exceed $\frac{1}{2}$ cub. cent. (7.717 Tr. grs.) of the prepared standard solution of soda, and after every new addition, place a drop of the mixture upon neutral blue litmus paper; as soon as the spot covered by the drop does not become red any longer, the analysis is finished; being careful that the neutrality is exact, and that there is not an excess of the soda solution. We then determine by calculation, from the amount of caustic soda, standard solution, used, the amount of oxalic acid which would be equivalent to the amount of unknown acid actually contained in the urine. The average amount of free acid discharged in a state of health is equivalent to from 2 to 4 grammes (30.868 to 61.736 Tr. grs.) of oxalic acid.

and mucus, and minute portions of urine already in a state of alkaline decomposition.

Abnormal urine may be voided in an alkaline or neutral state, or it may become so shortly after its emission. A neutral or alkaline condition of the urine is due to the presence of fixed or volatile alkalis, more generally carbonate of ammonia, which is formed from the decomposition of urea. Ammoniacal urine is always pale, fetid, and turbid from the presence of phosphate of lime and triple phosphates; urine which is alkaline from the presence of bicarbonates is usually clear. If there is just enough alkali present to neutralize the free acid of the urine, then this fluid, being neutral, will not exert any influence upon either blue or reddened litmus paper; but when there is an excess of alkali, the urine colors blue litmus paper red.

Animal food has a tendency to diminish the acidity of the urine, and even cause it to become alkaline; the use of apples, lemon-juice, and many acid fruits produces similar results. But the alkalinity, which occurs after using these articles, is not persistent, and is of no practical importance. But an alkalinity due to the presence of volatile alkalis, or to the administration of alkalis and earths or their carbonates, for an unreasonable length of time, is always indicative of disease, as, stone in the bladder, inflammation of the mucous coat of the bladder, weakness of the bladder, urethral stricture, enlargement of the prostate, paralysis, spinal disease, great weakness and prostration, etc. The urine is also alkaline in typhus fever, coma, and in the decrepit state of aged persons.

The diagnosis of disease or the determination of a remedy, from the acid or alkaline character of the urine, should never be based upon the reaction of a single specimen of it, but upon that of several, procured at different periods. Ammoniacal urine, when due to retention of this fluid, or to certain conditions of the bladder, is best removed, and the urine restored to its acid state, by washing out the bladder at several different times with warm water, by means of a syringe and double canula. Where this course is ineffective, and the urine continues pale and alkaline, tonics and preparations of iron are indicated.

The specific gravity of urine enables us to determine the amount of fluids and solids contained in it. The ordinary manner of ascertaining the specific gravity, and which, though not absolutely correct, is sufficiently so for practical purposes, is by means of a correctly graduated urinometer. Those instruments of this kind, whose scales are divided into equal parts are erroneous, being based upon the supposition that the strata of the urine is also of equal

density. But this is not the case; the density of this fluid increases with the depth from the surface, and the scale should be graduated according to the different densities of the respective columns of urine. When determining the specific gravity of urine, it should be brought to a temperature of 60° F., else erroneous conclusions may be arrived at.

As already stated, the specific gravity of healthy urine ranges from 1.003 to 1.030, averaging from 1.015 to 1.0120, the variations being due to the varying amount of water and of solids which it contains. We can not determine the particular ingredient which is affected, by the specific gravity, but we can tell the aggregate amount of solids present in the urine. This is determined as follows, for urine whose specific gravity does not exceed 1.018: double the last two figures expressing the specific gravity; the product shows the number of parts (or grains) of solids contained in any thousand parts or grains of urine. Thus, urine of a specific gravity, 1.014, contains 28 grains of solids in every 1000 grains of fluid.

Where the specific gravity exceeds 1.018, multiply the last two figures expressing it by 2.33, and the result is the number of parts of solids contained in any thousand parts of urine; thus, if the specific gravity be 1.025, the urine contains 58.25 parts of solids in every 1000 parts.

By determining the amount of solids in 1000 parts of urine, we may, if we have ascertained the amount of urine voided in twenty-four hours, easily calculate the whole amount of solids secreted with it by the following rule: as 1000 parts is to the parts of solids contained in this amount, so is the weight of the whole amount of urine passed in the 24 hours, to the amount of solids contained in it. Thus, a patient passes 8500 grains of urine in 24 hours, of specific gravity 1.015; what amount of solids did it contain?

grains.	grains.	grains.	grains.
1000	: 30	: : 8500	: 255, the whole amount of solids.

This method, however, merely gives approximative results; where any approach to accuracy is required, a given quantity of the urine, say 1000 grains, must be evaporated to dryness at a low, even temperature, and the solid material remaining be weighed.

The object, then, of ascertaining the specific gravity of urine, is to determine the quantity of solids passed with it. The maximum amount of solids passed in health in twenty-four hours is 1234.72 grains; the minimum quantity is 617.36 grains; and the mean quantity, 926.04 grains. Any great and constant departure from the mean amount leads to a supposition of abnormal action, which should be carefully investigated by the practitioner.

The specific gravity of the urine, and consequently the amount of solids present is subject to very great variations, as the result of both functional derangement and disease. Thus, urine of very low specific gravity is the result of a retention of urea and other elements of urine in the blood, or of an impaired eliminative power of the kidneys, as in chlorosis, many hysterical and nervous affections, structural disease of the kidneys, etc.; in which cases the quantity of urine is also much diminished, and more or less albumen is present. In chronic disease where the amount of solids has been diminished, but is gradually increasing under treatment, it is a prognosis of improvement, except in diabetes mellitus, where an increase of solids in the urine is indicative of an increase in the severity of the disease.

In acute diseases, when there is an increase in the amount of solids in the urine during the height of the disease, it indicates an excessive disintegration of the tissues and juices of the body, which must lead to exhaustion of the system, and is an unfavorable symptom. A constant and gradual decrease of the amount of solids is as unfavorable as a diminution in the quantity of urine passed, because it indicates the decay of life. A small amount of solids with a small quantity of urine, is indicative of anemia, or, disease of the kidneys. If the quantity of fluid be very large, while the amount of solids is small, it may be due to excess of drink, or may accompany hysteria, anemia, etc.; this condition of the urine has been called "hydruria," and is considered a favorable symptom in dropsy and anemic conditions generally. When the urine is small in quantity and the amount of solids, although larger than in the preceding instances, is still below the normal standard, it indicates acute disease. When both the solids and water are present in excess, it is an indication of diabetes; diabetes mellitus if sugar is present, and diabetes insipidus if the increased amount of solids is due to other matters than sugar. When urea is retained in the blood, in consequence of disease of the kidneys, it gives rise to drowsiness, stupor, dropsical effusions and death.

When healthy urine is allowed to rest for a short time, a small, light, grayish-white cloud gradually settles toward the bottom, which is composed of mucus and epithelial scales. The normal amount of mucus passed in twenty-four hours is about 7.28 grains; but the eye should be accustomed to estimate the proper amount in urine by frequent inspection of urine in glass vessels by transmitted light. The mucus is principally derived from the bladder and urethra; the epithelium from the kidneys, bladder, urethra, and va-

gina. Dilute tincture of iodine added to the urine in small quantity, preeipitates and colors the mucus.

Alkalinity of the urine from deeomposed urea, as well as a large quantity of free acid may cause an exeess of mucus in the urine; so also will stone in the bladder, irritation of the bladder and urinary passages, as well as other diseases of these parts, as stricture, irritable prostate, paralysis or eatarrh of the bladder, etc. When there is an exeess of mucus in urine, that fluid soon undergoes putrefaction; and albumen is seldom, if ever, present.

In the eatarrh of the bladder of old people, mucus is largely secreted, and astringent remedies by mouth, and by injection into the bladder, with tonics internally, are indicated.

The character of the epithelium met with in the mucus, when in exeessive amount, and which can only be ascertained under the microscope, also assists in determining the location of the diseased parts from which they have been thrown off. Pelvic epithelium is never found in healthy urine; its presence there is indieative of disease in the pelvis of the kidneys; while renal epithelium in urine is always an evidence of disease of the renal tubes,—a more or less rapid desquamation of them. The disease is worse when the epithelium is mixed with fatty products,—fatty degeneration of the kidneys. Cancer cells indicate caneer of kidney or bladder, or both. Bladder epithelium in increased quantity indicates more or less catarrhal inflammation of the bladder.

The normal constituents of urine are as follows:

1. *Urea*, $C_2 H_4 N_2 O_2$, is the principal product of the metamorphosis in the body of nitrogenized food, which, ineapable of being more highly oxidized, can no longer serve the purposes of life, and is therefore excreted by the urine; it possesses neither an acid nor an alkaline reaction. Urea is formed in the blood, from which it is separated and eliminated by the kidneys; but if these organs be diseased, the urea, failing to be excreted, accumulates in the blood, upon which it acts as a poison, and produes many serious and even fatal symptoms, especially of the brain. The maximum amount of urea in healthy urine is about 688.2 grains in twenty-four hours; the minimum amount, in the same time, is 286.1 grains; and the mean amount is 512.1 grains. During waking hours, or during physieal and mental exertion more urea is produeed than during sleep, or during an equal period of inactivity. A large amount of nitrogenized food causes an increase of urea; while a small amount of vegetable food produes a diminution of it.

Urine containing an exeess of urea, is usually clear and free from sediments, of rather a dark yellow color, of a strong urinous smell,

and has a specific gravity of 1.020 to 1.030; its excess is owing to active oxygenation of uric acid, and is generally associated with derangement of the digestive functions, as well as of the cutaneous, and also with plethoric conditions of the system. It is common in the severe stages of most all acute and inflammatory diseases, pyæmia, septæmia, diphtheria, convulsive paroxysms, rheumatism, diabetes insipidus, and in urine depositing oxalate of lime. The treatment is to lessen this inordinate waste of tissue, by regulating the bowels, exercising moderately, light diet, diaphoretics, sedatives, keeping the skin in a healthy condition by bathings and frictions, cool water donches to the head and back, and avoiding hard study, violent exercise, etc. In severe dyspepsia, in addition to the above, vegetable and chalybeate tonics may be given. Alcohol, tea, and coffee lessen the amount of urea, while common salt and alkalies increase it.

Urine containing a deficiency of urea has a specific gravity of 1.001 to 1.008, and the quantity of urine excreted is usually increased. Its deficiency is due to a limited production of urea in the blood, as well as to a failure of the excretory powers of the kidneys; when urea is retained in the blood it gives rise to a group of symptoms termed "uræmia." Deficient urea is met with in anemic conditions, hepatic dropsy, cirrhosis, chronic nervous affections, as hysteria, neuralgia, epilepsy, and most convulsive diseases, paralysis, chlorosis, acute yellow atrophy of the liver, Asiatic cholera, following a fit of asthma, jaundice, last stage of cancer of the liver, chronic Bright's disease, and in most chronic and nervous diseases. The treatment is to stimulate the kidneys by exercise and diuretics, and to aid in the elimination of urea from the blood by keeping the bowels and skin in a healthy condition, and by stimulating the cutaneous functions from time to time; medicines to influence the liver, and alteratives to improve the character of the blood and nervous system, are also indicated, as well as vegetable tonics, chalybeates, and an abundant nitrogenous diet.

"If, in cases of fever, such as typhoid and typhus, or of the exanthemata, such as small-pox and measles, or of inflammatory affections, such as pneumonia and meningitis, a decrease in the daily elimination of urea is observed, it may be regarded as a most favorable sign for the prognosis; for no sooner does a change for the better take place in these affections, than an immediate diminution in the amount of urea is observable. During convalescence the quantity is frequently below the normal standard; whereas, in cases tending to a fatal termination, even in spite of the true febrile symptoms having passed away, the daily excretion of urea still remains

high. Hence this sign may be a valuable and truthful guide when all others fail. If, on the other hand, in those diseases in which the excretion of urea is known to be abnormally small, such, for instance, as paralysis, cholera, or the different forms of albuminaria, an increase in its amount during the course of the case is noticed, it is an equally favorable sign for the prognosis; while, on the contrary, any further reduction in the amount of the eliminated urea can not be otherwise regarded than a most untoward event, as, even when the other symptoms have improved, it is an almost infallible index of approaching danger." (*G. Harley.*)

2. *Uric Acid*, $C_{10}N_4H_4O_6$, also called "*Lithic Acid*," is a constant normal ingredient of the urine; it occurs in the blood as urate of soda, or urate of ammonia, from which it is set free either when it reaches the kidneys, when the urine containing it reaches the bladder, or after the urine has been voided. The maximum amount of uric acid in healthy urine is about 14.49 grains in twenty-four hours; the minimum amount, in the same time, is 4.32 grains; and the mean amount is 8.56 grains. Uric acid is common to persons who indulge liberally in a meat diet and alcoholic drinks, as well as to persons of sedentary habits. When uric acid deposits occur constantly from day to day, it is an indication of disease; but their occasional presence, especially when occurring after the urine has stood for a long time, is of but little importance. Urine containing an excess of uric acid is usually scanty in quantity, of an acid reaction, and high color, and gives dirty-white, blue, black, yellow, pink, or red deposits, generally mixed with urate of soda or ammonia, mucus, etc., which adhere to the sides of the vessel containing it, forming incrustations thereon; the urine has a specific gravity of 1.020 to 1.025. An excess of this acid is due to a deficient oxygenation, which prevents it from being converted into a soluble urate. A few drops of nitric or hydrochloric acid to urine will facilitate the deposition of uric acid. Uric acid in excess is met with in the urine of persons laboring under gout, rheumatism, diseases of the liver, especially congestion of that organ, as well as cancer, in which it is in excess with amorphous urates, likewise cardiac affections, chronic diseases of the respiratory organs, chronic bronchitis, emphysema of the lung, pneumonia, various forms of skin disease, chorea, dyspepsia, febrile diseases, diseases of the reproductive organs, injuries or excessive straining of the loins, several other chronic diseases, etc. The crystals of uric acid occur in an innumerable variety of forms, all of which may be referred to some modification of the rhombus, square or rectangle.

In cases of excess of uric acid, the object of treatment is to

favor the further oxidation of the uric acid formed, and to promote its solution and elimination from the blood as rapidly as possible. For this purpose, good air and moderate exercise daily, are required, together with an especial attention to the functions of the skin, regularity of bowels but not active purgation, proper diet, and an improvement of the digestive powers by appropriate tonics, alteratives, and alkalis, as carbonate of potash, acetate of potash, phosphate of soda, borate of soda, phosphate of ammonia, etc.—but it must be remembered that although alkalis may cause the deposit of uric acid to disappear, they will not always correct the original fault or error which occasioned the deposit. Borax must be avoided among pregnant females. Wine, beer, and excess of animal food should be prohibited. In anemic persons preparations of iron may be administered. If the excess of uric acid be due to disease of the liver, tonics, alteratives, podophyllin, leptandrin, dandelion, colchicum, etc., are indicated, as well as diuretics, *epigæ repens*, *eupatorium purpureum*, etc. If it be due to a gouty or rheumatic tendency, colchicum, *cimicifuga*, *caulophyllum*, *veratria*, iodide of potash or ammonia, etc., are indicated. In febrile and inflammatory diseases, antiphlogistic and febrifuge remedies are required; in cases of cold, or a chill, whereby the action of the skin is checked, diaphoretics and a warm bath or two, will soon lessen the uric acid excess. In most cases, the use of ripe fruits containing acetic, citric or tartaric acids in combination with an alkali, will prove beneficial. Remove the cause, and in all cases the excess of uric acid will gradually disappear.

3. Although free uric acid may be deposited in the urine, it is very often met with, combined with certain bases, and colored with normal or abnormal pigment, forming “yellow, lateritious, brickdust, or fever” sediments. The most common base with which it is combined, is soda—less frequently with potash or lime—and still less commonly with ammonia. All urates are either insoluble, or only slightly soluble in water.

The addition of nitric, hydrochloric or acetic acid to urine containing urates, gives rise to their decomposition followed by a precipitate of free uric acid.

a. Urate of Soda, $C_{10} H_3 Na N_4 O_6$, forms the most common urinary sediment, it is soluble in boiling water, but precipitates as the solution cools, in short hexagonal prisms; thick six-sided plates forming sometimes star-like groups; round, yellowish or white opaque masses, with projecting processes. In the urine, urate of soda is usually amorphous from the presence of chloride of sodium, and is accompanied with urates of ammonia, lime or

magnesia, giving rise to a high-colored, dense, turbid, and slightly acid urine; sometimes, however, it is neutral or even alkaline. If the urine be pale, becoming opaque on cooling, its specific gravity will be about 1.012; if it be of a pale amber color, giving a copious fawn-colored deposit on cooling, its sp. gr. will be about 1.018; if it be high colored, giving a reddish-brown, or brickdust sediment on cooling, its sp. gr. will be about 1.025. The indications and treatment, are similar to those named for uric acid.

b. Urate of Ammonia, $C_{10} H_3 (N H_4) N_4 O_6$, generally occurs in urine as a dark, granular, perfectly amorphous precipitate, on cooling; in disease, it is usually met with in the brick-red or pale fawn-colored sediments, which are dissolved on heating the urine; urate of ammonia is the only urate which gives off ammoniacal fumes when heated in a solution of caustic potash or soda.

c. Urate of Lime, $C_{10} H_3 Ca N_4 O_6 + 2 Aq.$, occasionally occurs in the urine in small quantities; it also forms the gouty tumors met with near the joints.—The *bi-urates* of *lime*, *ammonia*, *magnesia*, and *potassa* are also found in urinary deposits, especially the first three.

4. *Creatine* and *Creatinine* take their origin in the disintegration of the muscular tissues, and when their amount is abnormal, there must be undue waste and disintegration of the muscular tissue, due to over-exertion, or wasting induced by hectic, marasmus, or active inflammatory disease. *Creatine*, $C_8 H_9 N_3 O_4 + 2 Aq.$, is soluble in boiling water, and is deposited in the form of transparent, brilliant, and pearly crystals, of variously modified forms of the right rectangular or right rhomboidal prism. Healthy urine usually contains a small quantity of creatine; about 4.7 grains is the average amount passed in the course of 24 hours by persons in health.

Creatinine, $C_8 H_7 N_3 O_2$, is the product of decomposition of creatine; it is more soluble in water than creatine, restores the blue color to reddened litmus, and is deposited in the form of right rectangular prisms. In healthy urine, about 7 grains is the average amount of creatinine passed in 24 hours. The treatment in excess of creatine and creatinine must be according to the cause of the wasting of the muscular tissues.

5. The normal *coloring matter* of urine (*urohæmatin*) is derived from hæmatin or pigment of the blood, and has been called "uræmatine," or "urophæine." Uræmatine gives to healthy urine its various shades of color according to the quantity of it present in this fluid. The amount excreted in 24 hours has not been

determined, though it is considerably increased in fevers and typhoid conditions, while in chlorosis, anemia, hysteria, and nervous diseases its quantity is diminished.

6. *Hippuric Acid*, $C_{18}H_9NO_6$, is a normal constituent of urine, though it is not always present; it is usually formed by the decomposition of benzoic or cinnamic acids taken internally. It is not found in the urine of animals that live exclusively on meat; but among vegetable feeders, the more exclusive the diet the greater is the increase of the hippuric acid. This acid crystallizes in long, glistening, transparent prisms, having four sides, and is soluble in hot water and alcohol. It never forms a deposit in urine, but is obtained by concentrating the urine, then adding half its bulk of hydrochloric acid, and allowing it to stand for a few hours. When present in excess in the urine, that is, when more than about 10 grains is passed every 24 hours, (and not produced from the diet,) it indicates deficient action of the lungs, skin, and liver, or the use of food deficient in nitrogen. Hippuric acid has been found in the acid urine of fever patients, and in diabetic urine.

Urine containing excess of hippuric acid, is usually faintly acid, neutral, or alkaline, having a whey-like odor, a specific gravity of 1.006 to 1.008, and frequently holding triple phosphate of magnesia; the quantity of the urine being commonly in excess. The means of treatment are nitrogenous diet, and less food containing excess of carbon; moderate exercise daily in the open air; chalybeates; attention to the skin and bowels, as well as the liver and lungs.

7. *Chloride of Sodium*, $NaCl$, is found in various proportions in urine, depending upon the quantity ingested with the food; the average amount per 24 hours being from 154.34 grains to 200.642 grains, or a medium quantity of 177 grains. The range above and below this mean may, however, vary from 30 to 60 per cent., or more. The amount of chlorine discharged by an individual varies on different days, according to and corresponding with the amount of chloride of sodium taken with his food; the largest amount of chlorine per hour, is secreted a few hours after the largest meal of the day, the smallest amount is invariably secreted during the night, as the secretory activity of the kidneys, as regards chlorine, appears to be diminished during rest and sleep, while mental and bodily activity will increase the secretory activity of the kidneys, for chlorine, at any time during the day and night.

In all acute febrile diseases, the amount of chlorine discharged in the urine sinks rapidly to a minimum, until, in certain cases, it disappears entirely for a short time; when the diseased action is

abating, the amount of the chlorides rises during convalescence, sometimes above the normal average. In chronic diseases the excretion of chlorine is generally diminished. As the chlorine diminishes in quantity the more serious becomes the prognosis; as it rises in amount, the indication is a returning to health. In urine, chloride of sodium always appears in octohedral forms; and urine containing a normal amount of urea, will, if chloride of sodium be present, when evaporated, show the urea in the form of crosslets and daggers, under the microscope. Besides chloride of sodium, urine also contains a certain quantity of chloride of potassium.

8. *Sulphuric Acid*, and *Sulphates* in the urine are derived from the sulphates introduced with the food taken into the stomach, as well as from the oxidation of the sulphur of the albuminous matters contained in the body. The quantity of sulphuric acid passed with the urine in 24 hours ranges from 14 to 32 grains. The use of sulphuric acid, sulphur, sulphate of soda, and other sulphates as well as sulphurets, violent mental or physical exercise, and a purely animal diet, cause an increase of the sulphates in urine; while a purely vegetable diet causes the amount of sulphates to sink considerably below the average under ordinary mixed diet. In disease, no satisfactory results have been obtained as to the amount of sulphates in urine; in most acute diseases, as well as in chronic, the amount appears to be diminished, to a greater or less extent below the normal average. In diseases characterized by a considerable disintegration of muscular tissue, there will be an unusual amount of sulphate in the urine; as in chorea, acute rheumatism, certain skin diseases, etc., but not in typhoid fever, and scarlatina. Where but little food is taken, a considerable decrease of sulphuric acid occurs. A determination of the quantity of sulphuric acid is useful for determining the amount of disintegration of albuminous matters in the system, in cases where the ingestion of sulphur in any form or combination is very low or altogether suspended.

9. *Phosphoric Acid* in the form of *Phosphates* gives a very important class of salts which exist in greater or less quantity in all the tissues of the body, in the secretions, and in considerable proportion in the blood. The maximum and minimum amount of phosphoric acid discharged in 24 hours varies considerably, being from $18\frac{1}{2}$ to 75 grains; of which the mean amount of 37.01 grains of the acid is united with alkalis, and 8.62 grains with earths. Of the phosphoric acid eliminated in the urine in the form of phosphates, the greater proportion is doubtless taken in the food; but

a certain amount is formed in the organism by the oxidation of the phosphorus of albuminous tissues, which takes place during their disintegration. Much of the phosphoric acid formed in the organism is doubtless produced in the nervous tissue.

In acute but not very severe diseases, the amount of phosphoric acid in the urine decreases at first, most probably in consequence of the low diet, and afterward rises again with a more liberal allowance of food. During convalescence, the normal amount is sometimes exceeded, in consequence of an increased quantity of food. If the illness, though combined with violent fever, only lasts a short time, the decrease of the amount of phosphoric acid is sometimes very slight and scarcely perceptible.

When the diseases are of a more severe nature, so as to cause a long abstinence from food, or to take a fatal turn, the decrease of phosphoric acid in the urine becomes much more considerable. In some exceptional cases the amount of phosphoric acid discharged during the height of acute diseases, may considerably exceed the amount discharged during health.

In chronic diseases the excretion of phosphoric acid takes a very irregular course, and though remaining mostly below the normal average, may sometimes considerably exceed it.

The following are the phosphates more commonly met with in the urine:

a. Acid Phosphate of Soda, $\text{Na O}, 2\text{H O}, \text{PO}_5 + 12 \text{ Aq.}$, to which, in many cases the acid reaction of the urine is due; it may be obtained in crystals.

b. Ammonio-Phosphate of Soda, $\text{Na O}, \text{NH}_4 \text{ O}, \text{H O}, \text{PO}_5 + 8 \text{ Aq.}$, or microcosmic salt, forms beautiful transparent four-sided prisms, The two preceding alkaline phosphates are soluble in water, nitric, and hydrochloric acids.

c. Ammonio-Phosphate of Magnesia, $\text{PO}_5, 2 \text{ Mg O}, \text{NH}_4 \text{ O} + 12 \text{ Aq.}$, also called Triple Phosphate, Basic or Stellar Phosphate, forms rectangular prisms, as well as stellar and foliaceous crystals, the urine being clear, and of normal specific gravity. This salt is more common to the young. It is a combination of an alkaline and an earthy phosphate; is slightly soluble in water, but is rendered insoluble by the addition of a trace of ammonia.

d. Phosphate of Lime, (acid.) $\text{PO}_5 + 3\text{Ca O} + \text{H O}$, insoluble in water, and not constant in urine.

e. Phosphate of Lime, $3\text{Ca O}, \text{PO}_5$, a normal constituent of urine, and like the preceding phosphate insoluble, and amorphous.

All these phosphates have a white and lime-like appearance, and change to a golden yellow color by contact with a solution of

nitrate of silver. A deposit of the earthy phosphates is not a proof of their being in excess, as it may only indicate an alkaline condition of the urine. The alkaline phosphates are frequently in excess in acid urine, without being deposited.

Urine containing an abundance of earthy phosphates, may be dark-brown, greenish-brown, or whey-like, very fetid, alkaline or neutral, with dense, ropy mucus, and often tinted with blood; in some instances it will be acid when voided, but speedily becomes neutral or alkaline. One thousand parts of normal urine contain 1 to 5 parts of earthy phosphates.

When the urine is pale, or white like whey, specific gravity ranging from 1.005 to 1.014, alkaline, fetid, and giving a copious deposit of the phosphatic salt,—this condition of the urine may be due to some abnormality of the spinal marrow; to organic disease of the kidneys; exhaustion of the nervous system; marasmus, or renal calculi. The liver, skin, and bowels should be kept in as normal a condition as possible; moderate exercise should be taken, together with counter-irritation; use of vegetable acids; cold bathing with friction in drying; tonics; diuretic alteratives; nitro-muriatic or benzoic acid; colchicum; proper diet, etc.

When the urine is pale, fetid, faintly acid, of a greenish cast occasionally, viscid or gelatinous from abundance of puriform mucus, forming long, tough ropes when drawn out, which often interferes with its escape from the bladder, with a thick opaque creamy deposit, and specific gravity from 1.005 to 1.014, it indicates a diseased state of the mucous membrane of the bladder, enlarged prostate, or calculus. The bowels should be attended to, as well as the skin; moderate exercise; injections into the bladder of infusion of golden seal, etc.; internal use of balsam of sulphur, mucilaginous diuretics, and an avoidance of acid or greasy food. In this case the copious deposit of the earthy phosphates will be apt to have mixed with it a greater or less quantity of triple phosphates in the form of prisms. Among old persons this character of urine indicates serious disease.

When the urine is of an amber hue, acidulous or neutral at the time of voiding, frequently having urea in excess, and with a specific gravity varying from 1.025 to 1.030, it is indicative of irritative dyspepsia; mal-assimilation of food; irritability or exhaustion of the nervous system; depression of the vital powers, etc. Regularity of the bowels; activity of the cutaneous functions; moderate exercise; nutritious food of easy digestibility; tonics; diuretics; alteratives; strychnia, with traveling, are among the remedial means to be employed.

The presence of earthy phosphates in the urine is indicative of the alkaline condition of that fluid. But it must be remembered that animal diet increases the acidity of the urine, while vegetable diet makes it alkaline. An excess of earthy phosphates in the urine rarely occurs. If the precipitate of earthy phosphates is entirely amorphous, we may conclude that the alkali which caused it was not ammonia.

If, however, the precipitate contains crystals of triple phosphate, it indicates the presence of ammonia, arising most probably from decomposition of urea.

The alkaline phosphates in excess indicate a more than usual disintegration of tissues rich in phosphorus, or an unusual activity of the brain or nervous system, as, in acute mania, phrenitis, convulsions, etc.

10. The alkalis, *Potash* and *Soda*, in the form of phosphates, carbonates, or sulphates, exist in the urine in various amounts; there being a large proportion of the soda salts which predominate in the blood, and a small one of the potash salts which are found in considerable quantities in the muscles. The amount of potash passed in the urine during 24 hours varies from 26.36 grains to 107.77 grains; that of soda, from 79.75 to 171 grains.

11. The alkaline earths, *Lime* and *Magnesia*, occur in the urine in the form of acid phosphates in solution; they are also met with as deposits in alkaline urine, and as concretions in urinary calculi, of which they most frequently constitute the crust. As generally met with they are amorphous. The amount of lime passed in 24 hours in healthy urine varies from 2.33 to 6.36 grains; and of magnesia, from 2.53 to 4.21 grains. *Carbonate of lime* is rarely met with; *oxalate of lime* frequently.

12. *Iron* is found in healthy urine in various proportions, being derived from hæmatin, and forming a constituent of uræmatine. Its presence indicates the amount of iron which enters the blood when it is taken as a medicine.

13. *Silica* has been met with in the urine, in traces only, being derived from the use of wheat and other similar plants as food; also *alumina*, derived from the alum taken in eating baker's bread.

14. *Extractives*, which includes various substances, as pigment, creatine, creatinine, xanthine, hypoxanthine, xanthoglobulin, omichmyloxyde, certain acids, resins, substances containing sulphur and phosphorus, etc., are passed in the urine, as far as it is possible to ascertain to the maximum amount of 231 grains per 24 hours; minimum $92\frac{1}{2}$ grains; and mean amount of 154 grains.

The abnormal matters found in urine are :

1. *Ammonia* has been found in healthy urine, averaging about 10.8 grains in 24 hours; the minimum quantity being 4.63 grains, and the maximum 15.434 grains; but whether this ammonia is a healthy ingredient of urine, or is the result of decomposition of the urea in the urine by the means used to detect the presence of ammonia, is not yet satisfactorily determined. Ammonia exists as urate, lactate, also in combination with phosphoric acid and soda, and with phosphoric acid and magnesia; it is also present as chloride of ammonium. When the salts of ammonia are taken into the stomach, the ammonia passes unchanged through the system and is discharged in the urine.

As a general rule when the salts of ammonia are in the urine, they are formed in the acid, and especially in the alkaline fermentation of the urine. In acid pathological urine, as in typhus, measles, scarlatina, etc., the occurrence of ammonia is not unusual; in alkaline urine it is almost constantly present, from decomposition of urea.

2. *Blood* or any of its anatomical elements when present in the urine indicates active or passive hemorrhage; excessive congestion of the kidneys; renal calculus; rupture of capillary veins in the kidneys, their pelves, or ureters, or of enlarged veins in the bladder; vicarious menstruation; diseased conditions of the blood; mechanical violence; malignant diseases, etc. Blood corpuscles can be seen under the microscope. Fibrin, an albuminoid substance which spontaneously coagulates, is present in many cases in bloody urine, as well as when no blood corpuscles are present. Most commonly, when fibrin is in the urine, fat and albumen are also present, forming "chylo-serous urine." (*For detection of urohæmatin, see Anemia.*)

a. Most frequently the presence of blood in urine is a symptom of the first or acute stage of those diseases of the kidney which are caused by the entrance into the blood of a specific poison; such as acute desquamative nephritis.

b. Or its presence may indicate ulcerated cancer of the kidney.

c. Or it may be due to the mechanical effects of renal concretions, or to ulcerations set up in the pelves and calyces of the kidneys by these bodies.

d. Or it may be indicative of certain diseases of the bladder, as, vesical hemorrhoids, or, softening cancerous growths of that organ.

e. Stone in the bladder, as well as chronic cystitis accompanied by erosion or ulceration, frequently give rise to hemorrhage from that organ.

The treatment must be according to the nature of the affection, and the source of the hemorrhage; rest, gallic acid, astringent diu-

retics, astringent injections into the bladder, tonics, alteratives, perchloride or persulphate of iron, etc.

3. *Chylous urine* contains one, several, or all of the following ingredients, viz. : red-blood corpuscles, white-blood corpuscles, shreds and films of fibrin, albumen, albuminoid matter, and fatty matters. Chylous urine is milky and turbid, the milky character being due principally to the fatty particles. When coagula of fibrin are present in urine, which have coagulated after the excretion of the urine, it is indicative of acute desquamative nephritis. The causes of chylous urine are at present unknown ; it is peculiar to certain tropical countries. Chylous urine is generally acid, decomposes more readily than healthy urine, and forms a spontaneous, fragile, fibrinous coagulum ; when ether is added to it the fatty matter is dissolved, and on evaporation of the ether, the fat is left behind. In the treatment, large doses of gallic acid have given the best results.

4. *Casts of uriniferous tubules* are of several kinds, and can only be seen under the microscope ; as renal casts frequently occur in urine where there is no permanent disease of the kidneys, too much importance must not be attached to their temporary occurrence. When the serum transudes through the renal vessels it appears to be accompanied by a coagulable material which being effused into the urinary tubes, spontaneously coagulates there, forming a cast or mold of the tube, and entangling in its meshes any loose bodies, as particles of epithelium, etc., that may happen to be in the tube at the time. This cast is gradually washed out by the fluid secreted behind it, and finds its way into the urine ; its diameter and general characters, as well as the characters of the various substances entangled in it, enable us to ascertain the nature of the morbid changes going on in the tubes at the time the cast was formed. Thus,—if the epithelium be abnormally adherent, the cast will be very narrow ; if, on the other hand, the epithelium be removed, the cast will be of the width of the tube. Should the epithelium be disintegrating, the cast will afford evidence of the change. If in a state of fatty degeneration, fat cells will be entangled in it. In hemorrhage from any part of the secreting structure, blood corpuscles are present ; and when suppuration occurs, the cast contains pus-corpuscles. When the transudation of the coagulable material occurs in a tube to which the epithelium is intimately adherent, or in a tube whose walls are smooth, the cast will be clear and perfectly transparent. (*L. Beale.*)

When these casts are in considerable numbers, being constantly found in the urine for some time, their pathological indications are as follows :

a. *Epithelial casts* from the urinary tubules, often contain many perfect cells of renal epithelium, blood globules, free epithelium, and epithelial debris, and are generally accompanied with a considerable deposit of uric acid. They indicate acute nephritis, or the elimination of morbid substances from the blood by the kidneys. When they remain in the urine for some time, and are mixed with much blood or pus, the prognosis is unfavorable; when they are observed for only a limited period of time, it is favorable.

b. *Small waxy casts* are derived from tubes in which the epithelial lining is entire, and indicate a chronic disease of the kidneys, termed "non-desquamative nephritis." In some of these cases, symptoms of blood-poisoning come on, and a rapidly fatal result occurs.

c. *Granular casts* are indicative of chronic desquamative nephritis, and of degenerated condition of the epithelium of the urinary tubules. When they occur after the acute form of the disease, the prognosis is favorable; but it is unfavorable when they are found in persons subject to gout, etc.

d. *Casts containing fat* are indicative of fatty degeneration of the kidneys.

5. *Albumen* may be detected in urine by heating it, or by adding nitric or hydrochloric acid to it—either of which causes a white coagulum or insoluble precipitate to form; the urine should have a slightly acid reaction either naturally or by the aid of some acetic or other acid. Both heat and nitric acid should be used in testing for albumen, being careful not to employ too large nor too small an amount of acid. If the deposit or coagulum produced by heat, or by nitric acid, is not dissolved subsequently by nitric acid or by heat, it is undoubtedly albumen. It must be recollected that a mere drop or two of nitric acid added to albuminous urine, prevents the formation of a coagulum, although a large quantity of albumen may be present. In these investigations great care must be had that the test tubes employed are perfectly clean. The practitioner must not rest satisfied with one examination, but should institute several at various intervals.

Urine containing albumen may be pale or high-colored, acid, neutral, or alkaline, of variable specific gravity, as well as quantity, and usually contains epithelial scales, blood corpuscles, mucus, casts of the urinary tubules, and saline sediments. Albumen is never found in healthy urine; its presence indicates a temporary, chronic, or permanent disease of the kidneys, as, congestion; granular disease; fungus hæmatodes; anasarca following scarlet fever; consumption; disease of the heart; cerebral softening; disease of pancreas, etc.

The treatment will depend entirely upon the symptoms present, and the character of the disease.

6. *Pus* in urine can be determined only under the microscope; the pus-corpuscles are more or less globular, nucleated, and frequently present quiescent granules within their anterior. Water causes the corpuscles to swell up, become pale and indistinct; acetic acid renders them more transparent and exhibits their nuclei more distinctly. Urine containing pus is mostly slightly alkaline, sometimes acid or neutral, and is always albuminous; it deposits a pale greenish-yellow or cream-colored precipitate, which is readily diffused again by agitation. Upon heating the urine, the albumen present coagulates, and is not soluble in nitric acid. The presence of pus in urine may be due to suppurative inflammation of some part of the genito-urinary mucous membrane, as, of the urethra, prostate, bladder, ureters, pelves of the kidneys, or of the secreting structure of the organ; it may also be due to absorption of purulent matter, and to abscess opening upon any part of the surface of the genito-urinary mucous membrane. The treatment must be according to the location of the disease, its characters and symptoms. Gallic acid, alum, tincture of muriate of iron, geraniin, etc., with alteratives and tonics are indicated. If the pus proceeds from the mucous membrane of the urethra, or of the bladder, astringent injections will be useful.

7. *Semen* or *Spermatic Filaments*, in urine, may be due to nocturnal emissions, but are frequently met with in the urine of healthy persons wholly free from any disease of the reproductive or urinary organs.

8. *Bile* in urine imparts a very dark-yellow color to this fluid, sometimes reddish-brown, or greenish, together with a more or less bitter taste. To detect the coloring matter of bile, (*biliverdin*), spread a few drops of the urine over a white, china plate, so as to form a thin layer, then allow a drop of nitric acid, containing some nitrous acid, to fall upon the center of this layer. If bile be present a blue color will appear in the circle of urine formed; this will enlarge towards the circumference of the plate, and the circle next to the drop of acid assumes a violet color. The blue and violet circles expand, and an inner red circle appears. Or, if acetate of lead, in solution, be added to urine it will cause a yellowish precipitate.—If urine containing bile be allowed to stand for a few days, the crystals of triple phosphate which form will have a yellow tinge.—Pettenkofer's test will detect biliary acids in urine.

Bile may be present in the urine of healthy persons during hot weather. The bile acids are not always present in the urine in

jaundice, as they may be destroyed in the blood, but the coloring matter of bile is always present in this disease. When bile is found in the urine it indicates that the flow of bile from the liver into the intestines is impeded or entirely suspended.

9. *Leucine*, $C_{12}H_{13}NO_4$, or oxide of cheese, has been met with in the urine of patients with disease of the liver, and spleen, in rheumatism, tuberculosis, typhus, variola, etc.

10. *Tyrosine*, $C_{18}H_{11}NO_6$, occurs in the urine of patients having the same diseases as those in which leucine is met with.

11. *Xanthine*, $C_{10}H_4N_4O_4$, is frequently met with in the urine in disease, but its pathological importance, as well as that of *Hypoxanthine*, $C_{10}H_4N_4O_2$, is not yet understood. The same may be said of *Sarcine* or *Carnine*, $C_{10}H_4N_4O_2$; *Allantoine*, $C_8H_6N_4O_6$; and *Inosite*, $C_{12}H_{12}O_{12}+4HO$.

12. *Cystine*, $C_6H_6NS_2O_4$, occurs in the form of calculus, as a sediment, and in solution. As a sediment it forms a white or light-fawn colored, amorphous, rather bulky deposit, or appears at once in six-sided plates or rosettes, which are readily soluble in aqueous solutions of ammonia, potash, soda, lime, and oxalic acid. Urine containing cystine is of a pale greenish-yellow color, feeble acidity, or neutral, soon becoming alkaline, low specific gravity, commonly deficient in urea and uric acid, and often a peculiar sweetbriar-like odor, and, when decomposed, evolves sulphuretted hydrogen. Mucus, epithelium, and ammoniaco-phosphates of magnesia are very usual. Acetic acid precipitates cystine when in the urine. Cystine contains nearly 27 per cent. of sulphur. The pathological value of cystine is not well known, but supposed to be perverted assimilation of the albuminous and gelatinous tissues; imperfect or perverted secretion of bile; deficient oxidation. Cystine has been met with in chlorosis, anemia, scrofula, etc.; the ordinary symptoms connected with its appearance, are occasional pain in the back, debility, pallor of skin. The general therapeutical indications are to correct the condition of the liver; improve the state of the assimilative functions; diet, air, exercise, etc. Chalybeates in chlorosis and anemia. Cystine very much resembles *Taurine*, $C_4H_7NO_6S_2$, which is derived from the decomposed bile acids, and contains about 25 per cent. of sulphur.

13. *Grape or Diabetic Sugar*, $C_{12}H_{12}O_{12}+2Aq.$, although sometimes met with in small quantity in healthy urine for a short time, occurs in large quantities in diabetes mellitus as a constant ingredient. The urine is usually of a very pale color, clear and greenish, of specific gravity 1.025 to 1.055, and possesses a peculiar odor which has been compared to that of violets, new hay, apples,

whey, musk, sour milk, and horse's urine. Sometimes the specific gravity is of the healthy standard. The urine is passed in large quantities, is apt to be deficient in urea, generally has an acid reaction, and a sweetish taste. The presence of sugar in the urine is supposed to be due to mal-assimilation of saccharine matters. *Acetone*, $C_6 H_6 O_2$, has been discovered in diabetic urine, and probably imparts to this its peculiar odor.

14. *Oxalate of Lime*, $Ca O, C_2 O_3 + 2 Aq.$, crystallizes in well-defined octohedra, having one axis much shorter than the other two, and it also occurs in the form of dumb bells. Urine containing oxalate of lime is generally of a dark-amber color, of decided acid reaction, occasionally neutral or alkaline, of specific gravity 1.015 to 1.025, and, in most cases, contains urea in excess. Oxalate of lime is often found associated with other deposits, as, abundant urate of soda, or of earthy phosphates, also, of epithelial cells. Sometimes the urine is of a greenish tint, with the coloring principle of blood present; when it is pale, the specific gravity is low. Oxalate of lime, whether in the form of crystals or dumb bells, may be seen under the microscope; they may be formed in the tubes of the kidneys, in the bladder, or, as is more commonly the case, after the urine has been voided. These crystals or dumb bells are found in the urine in a vast number of diseases. Their presence in urine may indicate:

a. That oxalic acid or any of its compounds has been introduced into the stomach, as an ingredient of food, as a medicine, or as a poison.

b. When in considerable quantity and for a long period of time, during which the ingestion of oxalic acid, in any form, into the stomach was excluded, it indicates the existence of a disorder, the nature of which is, at present, wholly unknown.

c. Oxalate of lime is frequently found in not very small amounts, in the urine of patients recovering from severe diseases.

d. A small amount of oxalic acid, not permanent in its appearance, is of no pathological importance.

e. The presence of oxalate of lime in urine, may indicate disease of the kidney.

Oxalic deposits are probably due to deficient oxygenation, and to mal-assimilation of food in primary digestion, and are generally found in diseases where there is great depression of the vital forces, irritation of the spinal marrow, or, serious functional derangement of the digestive organs. They are also met with in careworn persons, among those who over-exert their brains in literary, scientific, business, and other studies, who masturbate or commit

sexual excesses, who live high but take too little exercise, etc. As a general rule any thing which improves the general health and promotes oxygenation, will diminish the tendency to oxalic deposits, as, cold bathing, exercise, attention to diet, bitter tonics, iron, nitric acid, hydrochloric acid, etc.

With this brief reference to the ingredients met with in healthy and unhealthy urine, I close this part of the work. It is impossible to enter into a full detail of these matters in a work like the present. However, those who desire to become fully instructed relative to normal and abnormal urine, its ingredients, and methods of detecting them, and determining their quantities, as well as their pathological importance, the diseases in which they occur, and the treatment, are referred to the following valuable works, from several of which, the preceding matter relative to the urine has been compiled:

Thudicum's Pathology of Urine; Beale on Urine, Urinary Deposits, and Calculi; Parkes on Urine; Bird on Urinary Deposits; Bowman's Medical Chemistry; Neubauer and Vogel on the Urine, etc.

PART II.

REMARKS CONCERNING THE CAUSES, SYMPTOMS, CURABILITY, AND TREATMENT OF CHRONIC DISEASES.

A KNOWLEDGE of the causes of chronic diseases will be of great value to the practitioner, not only enabling him to indicate them to persons in health who may consequently avoid them, but, in the treatment of this class of diseases, especially in their early stages, affording him great and effectual aid, as he may thereby more advantageously advise his patients of the circumstances and conditions of which they may avail themselves, and, at the same time, prohibit exposure to those causes which tend to produce or perpetuate disease. These causes should be classified, and their importance shown, as well as their relations or tendencies.

The difference between Acute and Chronic Diseases, may be briefly summed up, thus:—Diseases, more or less severe in their character, which are accompanied by feverish or active inflammatory symptoms, affecting the circulation and the nervous system, which run through their course rapidly, requiring prompt and active treatment, terminating in a few days or weeks in health, chronic disease, or death, are *acute*; while those diseases, more or less severe in their character, which affect one or more organs of the body, without being accompanied by feverish or active inflammatory symptoms, which require steady, long-continued treatment, and which progress slowly, terminating, after months or even years, in health, or in death, are *chronic*. Acute disease being confined more especially to the fluids of the system, may result in the return of the fluids to their normal condition; in a partial return to their healthy state, with abnormal action of one or more organs, (chronic disease); or, in decomposition of the fluids, or solids, or both, (death). Chronic disease, on the contrary, seldom manifests itself until some solid tissue becomes affected, although the fluids may have been in an abnormal condition for an indefinite

length of time previously; and a person may be suffering from chronic disease in the fluids of the system without having any suspicion of the fact, until the functions of some organ become so deranged as to give rise to marked symptoms. This description of the difference between acute and chronic forms of disease will answer for all practical purposes.

The causes of chronic disease, with the exception of those which are secondary, accidental, or coincidental, are but few in number, and a careful investigation of them will demonstrate that their principal influence is, as a general rule, exerted upon the cutaneous functions, diminishing, suppressing, or changing the character of the insensible perspiration, and is also, but with less intensity, exerted upon the respiratory passages. The influence of these causes is transmitted to internal organs through the agency of the nervous and vascular systems,—by means of the first, the impressions are conveyed to the solids, producing irritation in them; by means of the last, the effete matters, which the skin ought to eliminate from the system in the form of insensible perspiration, are mingled with the blood, altering its elementary composition to a greater or less extent, and causing the local lesions met with in both acute and chronic diseases. What the special action of the perspiratory elements may be in effecting alterations of the blood, and in producing local lesions, we have but a limited knowledge; yet, from the fact that these elements consist principally of worn-out and devitalized matters of the system, we must conclude that their retention is a cause, probably the most frequent cause of the morbid changes observed in the fluids in many diseases. Besides, it is well known that when the skin in a state of perspiration is suddenly exposed to cold, persons so influenced become ill, the character and severity of the disease varying according to the age, sex, temperament, resisting power of the system, season, climate, and condition of the system or of some of the organs,—the several forms of disease, thus produced in different individuals, being due to one identical cause, viz., suppressed perspiration.

Among the causes of chronic diseases, moisture, want of exercise, atmospherical vicissitudes, locality, deprivation of pure air, and of sunlight, are the most prominent. Animals frequently die of chronic diseases, yet we do not hear of the disease or the death being attributed to intemperance or other vices of society, onanism, inhalation of animal, vegetable, or mineral powders, tight corsets, to a constrained position during work, etc. True, these are causes of chronic disease among the human race, but they are secondary, or accidental causes, as much so as when a disease is produced by a

severe blow or wound, and often exert but a feeble influence in the production of chronic disease. And with regard to these secondary or accidental causes I will say, that, to preserve health and promote longevity, an absolute avoidance of them is not only necessary for patients, but also for persons in health. The effects of secondary or accidental causes are especially to be observed in large cities, in which places chronic diseases are very common; the host of causes which concur in their production can hardly be separated by observation and analysis.

A moist atmosphere not only interferes with the evaporation of insensible perspiration from the surface of the body, but it also prevents the requisite amount of fluid in form of vapor being carried off through the respiratory passages, thus lessening the activity of the skin as well as of the lungs, from which diminished action more or less effete matter is retained in the system. If this suppression occurs suddenly, acute disease is the result, which may, according to its nature, severity, and therapeutical treatment terminate in health, chronic disease, or death; if it occurs slowly and continuously, the changes in the fluids are effected by degrees, and chronic diseases gradually manifest themselves. From this cause, chronic diseases are more numerous in moist climates, and in direct ratio with the declivity of the locations. If the moist air be in a state of rest, the evacuation of fluid from the surface of the body will be at its minimum; if, however, it be in motion, it will be more favorable, as air in motion facilitates the evaporation of the fluid exhaled by perspiration. It must also be recollected that moisture favors the development of microscopic fungi, so frequently met with both as a result, and a cause of disease.

Want of exercise has been named as a primary cause of chronic diseases; this, in connection with moisture, prevails over all other causes in the production of these maladies; the principal action of these two causes is exerted upon the skin, checking the functions of this organ, and repelling into the circulation superfluous or excrementitious elements which should be eliminated from the system, and which produce morbid changes in the blood, resulting in chronic disease of one or several organs.

The favorable influence of exercise upon the constitution of man, as well as the dangers accompanying a sedentary life, have been known for ages. In all localities, muscular exercise either in the open air, or in dwellings, is absolutely indispensable for the maintenance of health; it is by motion that life is manifested, that the constitution acquires and preserves its energy. A sedentary life diminishes the expansive action of the nervous system, the activity

of the circulation ; it tends to determine the blood from the external capillary system to the internal or visceral ; the capillary circulation becoming enfeebled, the excretory functions of the skin become inactive, and congestions occur in the organs, eventually giving rise to chronic diseases.

Notwithstanding the influence of moisture in causing disease, we find, even in instances where secondary causes are also present, as bad food, inhalations of various powders, noxious emanations, improper ventilation, etc., that the expansive and sudorific action of muscular exercise in the open air is sufficient to advantageously counterbalance the influence of dampness and lowlands in very many cases. This is observed among those persons who are exposed to dampness during their hours of labor, but whose exercise preserves them from chronic diseases, with the exception, perhaps, of rheumatic pains arising from the influence of the moisture upon the skin, as, with dyers, soap-boilers, tanners, bleachers, etc. Exercise, in provoking perspiration, sustains the skin in a constant state of normal excitation. Yet it must be borne in mind that moisture exerts a general influence which muscular exercise can not always counterbalance; and it may even happen that in exciting perspiration, it will render one more readily susceptible to the debilitating and concentric influence of cold and moisture.

The freedom from disease among active persons has been attributed by some not to their exercise in the open air, but to their individual physical strength,—the effect being mistaken for the cause. Physical strength, undoubtedly, gives to man a long-continued resisting power to disease, but finally, unless he exercises, the causes of disease exert their baneful influence, and deteriorate his constitution.

The influence of exposure to atmospheric vicissitudes in producing disease is well known to all medical men, and, like the preceding causes, it is exerted chiefly upon the cutaneous and respiratory functions.—A deprivation of pure air prevents the blood from being properly oxygenized, from which results nervous debility and languid action of the cutaneous capillary functions.—Sunlight appears to exert an electric, vivifying, and salutary influence upon organic nature, as observed in the healthful appearance of organized bodies exposed to its influence, and in the degenerate condition of those deprived of its action. Vitality is refreshed and strengthened by the action of the solar rays, while their absence tends to depress, debilitate, and destroy. The high dwellings of cities, and the large and leafy trees placed around them, check the currents of air, tend

to keep up moisture, and interfere with the salutary effects of sunlight on the constitution of man. It is not only by its electrical action that sunlight favorably influences the human body, but also, by aiding in the evaporation of moisture, causing the insensible perspiration to be rapidly removed.

From this hasty glance at the causes of chronic disease, it will be seen that they all exert an influence, principally upon the functions of the skin, and, in a less degree, upon those of the pulmonary organs; and which facts will materially assist us in our treatment of this class of diseases. The secondary causes, as improper or insufficient diet, intemperance, etc., are so well understood, that I will not occupy the reader's attention with more than this reference to them, but will remark, however, that while investigating the primary causes of disease, we must take into account the elevation or the declivity of each locality, its dryness or dampness, the changes of temperature, difference in professions, customs, and regimen, the peculiar construction of the houses, as well as the nature of the soil upon which they are built, also the height and direction of mountains in the vicinity, if any are present. This accomplished satisfactorily, the physician may then direct his attention to the secondary or accidental causes which may have facilitated or even produced the disease which he is called upon to treat.

I may say here that there appears to be a certain condition of the fluids and solids of the body, as well as certain relations between them, which are necessary for that state termed "health"—or, in other words, an *equilibrium*. Whatever tends to maintain this equilibrium sustains and preserves health, and whatever deranges this equilibrium is a cause of disease; the greater the degree of derangement, and the longer it is kept up, the more severe will be the disease.

It is seldom, indeed, that actual disease is transmitted from parent to child, with the exception of maladies due to a poison or virus in the system, as, for instance, syphilis. Yet the *tendency* to certain forms of disease, as scrofula, consumption, rheumatism, etc., may pass in families from one generation to another, so that upon exposure to the exciting causes the disease will become developed. And I do not see how it could be otherwise; for a parent lacking in his own system those elements or vital qualifications necessary to the production and preservation of healthy glands, lungs, or muscles, etc., certainly can not be expected to endow his offspring with powers which he does not possess, but must, as it were, entail upon his children those deficiencies and tendencies to certain maladies which are natural to and form part of his constitution. This hereditary

tendency may be so active that the peculiar disease will start into existence, almost from birth, upon the slightest cause; or it may be so chronic that many years of exposure to the primary or secondary causes will be required in order to its development; or, one parent being healthy, the tendency to the peculiar disease of the other may thereby be rendered null, or be so modified as to require extraordinary causes for its production. And, between these extremes, various causes may lead to innumerable shades or degrees of predisposition to the parental malady.

I will here state, that notwithstanding what authors have said of hereditary diseases, I am fully satisfied, that, as a general rule, by a proper course of hygienic and therapeutic management, commenced early in life, and persistently continued in to adult age, such diseases, or rather the tendencies to them, are capable of being either wholly removed, or so modified as to preserve the person from subsequent attack of the parental disease; also that, in the latter instance, where there is a subsequent attack, a continuance of the modifying course for a few successive generations, will thoroughly eradicate the peculiar tendency from the family.

The character of the disease which may attack persons not possessing hereditary tendencies, and who have been exposed to the causes of disease, will depend entirely upon the nature of the morbid changes effected in the blood, influencing one or more of its various elements, as well as upon the degree of resisting power to disease possessed by the constitution, or by the organs of the body; thus, of several persons exposed to the same causes, one may have a tuberculous disease; another, a scorbutic; a third, erysipematous; a fourth, malignant; a fifth, anemic, etc.

As to which organ or organs may be attacked by the disease, this will depend principally upon their degree of departure from a strictly healthy condition, and the character of the blood disease, except in those cases, where, from temperament, certain organs are more disposed to attacks of disease than others. If those elements of the blood which are necessary for the vitality of the kidneys, are in superabundance, deficient, or diseased, these organs will be attacked; if it be the elements required for the life of the liver, which are in an abnormal state, this organ will be the affected one; if the morbid elements in the blood are those upon which the vitality of the osseous system depends, the bones will be the solid structures which must yield to the morbid influences.

Numerous elements enter into the composition of blood, as, water, fibrin, albumen, hæmatin, (an insoluble ferruginous substance), hæmato-crystallin, fat, extractive matter, cell-membranes, mineral

substances, chlorine, sulphuric acid, phosphoric acid, potassium, sodium, oxygen, phosphate of lime, phosphate of magnesia, etc. A deficiency or an excess of one or more of these elements, or the presence of some abnormal elements variously affecting the condition of the blood, must, necessarily, produce a disease corresponding with the character of the changes undergone by this fluid, and with the resisting power of the system, or, of certain organs, to attacks of disease; hence the variety of diseases, both as to character and location, which we are constantly observing. Attention has been turned of late to the chemistry of the blood, and indeed of the elements of the human body generally, but although considerable has been done, the matter is still in its infancy; further chemical researches are required, and other and more delicate tests have yet to be formed, before any very satisfactory conclusions can be arrived at.

In order to treat disease successfully and scientifically, the constituents of all the solids and fluids of the body, and their various relations with each other, should be well understood; likewise, the constituent principles of all remedial agents, and the various effects they are capable of producing when in contact with the elements of the body, both individually and collectively; then, we will have, a descriptive or nosological medicine, giving the symptoms or external signs; an organic medicine describing the lesions of organs; and an atomic, molecular, or chemical medicine, describing the molecular alterations of the fluids and solids, etc., and the changes they undergo by contact with each other and with remedial agents. Probably ages will pass before such knowledge will be perfected.

A chronic disease, no matter what organ or organs may be affected, is invariably the same; thus, a scrofulous or tuberculous disease is the same in all patients, whether it be located in the glands of the neck, the lungs, or the brain, etc; a scorbutic disease is the same, no matter where it may be located; and so, in other forms of chronic diseases. But the *symptoms* will vary according, to the nature of the disease, the organ or combination of organs attacked and their particular functions, the amount of disturbance effected in the organs, the character and scope of their sympathetic relations, and the degree of susceptibility or sensibility of neighboring organs. Thus, if disease attacks the lungs, there will be a series of symptoms developed which are in strict accordance with the character of the disease, the functions of these organs, and the degree of disturbance in them; if, instead of the lungs, the same disease attacks the kidneys, the difference between the symptoms developed in this case and in the previous one will be due to and in accordance with the

peculiar functions of, and the degree of derangement in, the kidneys. If, instead of the lungs and kidneys, the disease should locate in the brain, an entire new set of symptoms would be presented, in accordance with the functions, etc., of this organ. So that the same kind of disease may present a host of symptoms, very dissimilar to each other, but which are due to the circumstances just named. And it is from these differences in symptoms, that medical men are enabled to ascertain the character, severity, and location of disease.—A complication of two or more forms of disease may sometimes be met with, presenting symptoms in accordance with the character of the diseases, the condition of the system, and the nature and functions of the tissues or organs affected, etc., but such complications are comparatively rare.

There appears to be but three actions exerted on animal matter when under abnormal influences, viz.: irritation, inflammation, and decomposition,—the character and degree of each of which depends upon the nature and amount of unhealthy influence present, together with the condition of the parts acted upon and the surrounding circumstances affecting them. Thus we may have irritation produced slowly or rapidly, of varying degrees of severity and duration, which, if not removed, will be followed by a sudden or gradual attack of inflammatory action, of greater or lesser severity and duration, and, if not subdued, terminating in decomposition, as, induration, suppuration, fatty degeneration, tubercula, carcinoma, etc., or death. When these influences are suddenly brought into action, with more or less intensity, as a general rule, we have acute disease; when they occur gradually and with comparative mildness, we have chronic disease. Life itself, or vitality, is intimately associated with action, motion, chemical changes, or what may be termed a normal irritation, resulting in gradual decomposition of old tissues, and recomposition or the formation of new ones. When the irritation is abnormal the decomposition is in excess over the recomposition.

The character of the decomposition of internal organs is only to be observed after death, by dissection or post-mortem examinations. The study of the changes effected in organs or tissues by disease, is termed Pathological or Morbid Anatomy, and is of value inasmuch as it reveals to us the effects of disease upon organs, and sometimes enables us, in conjunction with our knowledge of physiological anatomy, chemistry, physiology, etc., to determine the true character of a disease as well as its proper treatment. “Yet it must not be supposed that it always enables us to arrive at such knowledge; indeed, the instances in which this happens are the exceptions and

not the rule. More commonly, dissection reveals to us, not the disease itself, but the terrible inroads it has made upon certain organs; and even then we do not witness these results in a living tissue, but in a dead mass. Hence, in a strictly practical sense, pathological anatomy, thus far, has proved of but little utility. For instance, in order to cure a disease, were it only required to know its location, its various forms, and its effects upon the affected organs, the treatment of pulmonary consumption would present the most happy results. In this disease, medicine has attained a high degree of perfection, and we have a most thorough knowledge of it, in the exact description of its symptoms, in the multiplicity of observations, in the profound anatomical researches which give to us the character of the morbid changes in the tissues, and in the ingenious method of exploration which enables us almost invariably to determine the seat of the disease. Yet, with all this knowledge, how inefficient are our means of treatment. Similar remarks may be made with regard to many other diseases, as, cancer, Bright's disease of the kidney, softening of the brain, certain incurable diseases of the heart, liver, ovaries, etc.

“What then is the practical result to be derived from the labors of anatomists who have given to us faithful and hideous descriptions of morbid organic changes? Their labors, it is true, are undoubtedly valuable, even if they accomplish no more than to enlighten us with exact descriptions in obscure cases. Yet, as descriptive medicine is at an end after it has given to us the description of symptoms, so pathological anatomy ceases when it reveals to us the morbid organic changes which caused the symptoms. The benefits to be derived from pathological anatomy are yet in the future, and will be perfected when its revelations are aided by those of descriptive and atomic medicine, heretofore referred to. At present, medicine is by no means an exact science, and notwithstanding our knowledge of physiology, anatomy, chemistry, etc., the cure of diseases is arrived at only by experiment and observation.”

Prof. Schultz, in his *General Pathology*, remarks: “Physicians open a body, and find hypertrophy of the liver, or hardness of the spleen, and conclude that the patient died from one or other of these affections! But they are blind to the fact, that hundreds pursue their daily avocations with enlarged livers and hypertrophied spleens, and that women can walk about with ovaria enlarged to the size of a child, till at last, being found in the dead body, it is presumed that death has ensued in consequence of these enlargements! Shall we never learn from such facts, that diseases do not originate from diseased masses and products, but that these same bodies are the effect

of disease, and the token that it has been present? Shall we never learn that the patient died, not from these pathological growths, but from the process of disease which called them into existence? and further, that we are not to direct our attention to the mere residues of disease, and the products of death, but rather to the destructive, or death-process itself?"

Alison, in his *Outlines of Pathology*, observes: "There are numerous cases arranged into different genera of disease; some of them very important and even rapidly fatal, for example, different forms of fever, certain cases of apoplexy and syncope, tetanus, hydrophobia, etc., which do not necessarily nor uniformly leave behind them, so far as is yet known, any alterations of textures, or other change perceptible to the anatomist, the pathology of which diseases, therefore, although it may derive assistance from, can not possibly be founded on the *knowledge of morbid appearances*." *Pathological Anatomy is not Pathology*.

The various pathological appearances of different organs which have labored under the same forms of disease, as revealed to us by dissection, are due, not so much to the disease itself, as to the nature and arrangements of the constituents entering into the composition of each organ. Thus, the structure and the character of the tissue of the lungs, kidneys, and brain are widely different from each other; when these organs indurate, ulcerate, or decompose from the influence of a tuberculous disease, it could not, certainly, be expected that each organ would present similar appearances to the dissector; the morbid changes observed in each organ must vary in accordance with its peculiar composition and organization, and the microscopic examination, as before remarked, will only show the effects of the disease upon the several organs, but will not expose the disease itself.

Believing as I do that the brain and nervous system are more deeply associated with the conditions of health or disease than any other organs, it seems to me that in all post-mortem examinations, the brain and spinal cord, as well as the ganglia, should be inspected; thus, we find a certain pathological condition of the kidneys, liver, or stomach, etc., let us ascertain whether a softening, hardening, or other change of the nervous centers is associated with these diseases, as well as which of these centers, and what part of them. The blood of the heart and lungs, which has now lost its vitality, should also be examined chemically, as soon after death as possible, in order to detect and compare any changes between it in a dead and in a living state, as well as any differences which may exist in it, in these two states, in various forms of disease.

I have several times referred to "the resisting power to disease;" this is a power inherent to every human being, being strong in some and quite feeble in others. The intensity of this power is due to the great vital force and physical as well as mental energy of the individual; it is this power that enables one apparently of delicate constitution to safely pass through a serious attack of sickness, while its deficiency or feebleness in the otherwise healthy and seemingly-robust man permits a fatal termination to his illness, provided the treatment pursued therefor does not destroy him. It is to this power and its degree of intensity, that of several persons exposed to the same cause of disease, some sicken and die, others sicken and recover, while others, again, have little or no indisposition whatever. Continued health and long life are owing to this resisting power, which should be strengthened and maintained by a proper hygienic course of living, because it is certain to be enfeebled or destroyed by imprudences or excesses, and by continued exposure to one or more of the causes of disease.

Every disease has its curable stage under proper treatment, and its incurable stage under any treatment. The curable period is during the early part of the disease, and before decomposition or organic changes have occurred in the organs or tissues affected; the incurable period is in the advanced condition of disease, when the organs or tissues affected have become hardened, softened, undergone fatty degeneration, or, become morbidly changed in some other way. Yet, it must be recollected that it has frequently happened that cures have been effected in morbidly changed organs or tissues, where these have held a minor relation to the vital actions and powers of the system; but, when the organs or tissues so changed have an essential and direct relation with the powers of life, a cure is rarely, if ever, accomplished. This is true both of malignant and non-malignant diseases.

For this reason, pulmonary consumption in its last stages, softening of the brain, fatty degeneration of the kidneys, etc., can not be cured by any treatment, more especially when the tissues are extensively implicated.

The curability of a disease, although depending principally upon the period at which treatment is commenced, is also influenced by other conditions and circumstances, as, the state of the patient's general health, or the condition of his fluids and solids, the business he pursues, the locality he inhabits, the changes to which he is necessarily exposed, the degree of resisting power he possesses, hereditary tendencies, the susceptibility of his system to the influence of remedial agents, etc., all of which should be noted by the

physician, that he may overcome them, or remove his patient from these influences as far as lies in his power. As a general rule, few chronic diseases admit of permanent cure, if treatment be instituted after the vital powers have passed into the descending scale, no matter at what age this may occur; from this cause but few thorough cures of chronic disease are obtained after the age of fifty, or among those who have brought on premature old age by improper conduct.

It is by no means uncommon for physicians, and even those of considerable experience and judgment, when certain malignant or suspected malignant affections or formations are presented to their professional notice, to advise the patients so afflicted to "let the matter alone," or, "to wait until it presents a more serious aspect, and demands treatment;" and the reason given for such advice is that, "the case is one of doubtful character, and any interference might cause it to assume a malignant form," or that, "by waiting until the true character of the disease is developed, they will be the better enabled to treat it." This is entirely wrong. The earlier any disease whatever is brought under proper remedial influences, whether medicinal or surgical, the more susceptible it is of being cured, if a cure is at all possible; and by delaying curable measures to a later period of the malady, is only to permit it to increase in severity or malignancy, and consequently to become less curable. There may be some rare exceptions to this course, due, for instance, to the location of the parts affected, which interferes in some way with local applications, or surgical measures; or, in which these applications and measures will seriously involve important tissues or organs, and thus perhaps hasten a fatal termination; in either of which instances, in the majority of cases, palliative measures will be the only beneficial ones,—a cure being entirely out of the question. Yet, as a general rule, the above remarks hold good.

The length of time required to effect a cure in chronic disease is a matter in which patients especially manifest much concern; it appears to be a popular prevailing idea, that if fevers and inflammatory diseases, which act so powerfully upon the system, prostrating the patient upon a sick bed for weeks with more or less intense suffering, can be cured in a few days or weeks, chronic diseases which present less intense symptoms and which do not confine the patient to his room, ought certainly to be cured in about the same length of time. And this erroneous opinion is frequently sustained by the course the medical man pursues, in

promising a quick cure, using mere palliatives to allay the symptoms and quiet the patient's anxiety, etc.

Acute diseases almost always attack suddenly, and are principally confined to the fluids of the body, and death would speedily ensue, especially in the higher grades where the tendency to decomposition is very great, did we neglect to quickly unlock the outlets for the elimination of morbid matters, and to lessen febrile or inflammatory action, adopting these measures with an energy or severity proportioned to the intensity of the acute attack. Hence, cures may be effected in from six hours to forty days, depending upon the nature of the disease, and the course of treatment pursued.

But with chronic diseases it is quite different; as a general rule, they are slow in developing themselves, from the fact that morbid materials are being constantly removed to a greater or less extent through the several excretory outlets of the body, and it is only when (from the continual retention and renewal of morbid changes in the fluids, the solids become abnormally influenced), the functions of an organ or set of organs become impaired, that the person realizes that he is laboring under some kind of disease. In acute disease an active treatment is the only true one; but in a chronic disease, the treatment must always be chronic if a permanent cure is aimed at; the remedies must act in a slow but constant and continued manner, and no sudden, magical, nor miraculous cures must be expected.

One of the most erroneous systems of practice, and one which is fraught with much danger, is the patching or palliating treatment, by which *symptoms* only are attacked, while the morbid changes giving rise to them are neglected or overlooked. Thus, a person suffering from pain, or a constant cough, applies to a medical man, who, instead of attacking the abnormal condition giving rise to his symptoms, merely palliates or deadens them by the administration of medicines which paralyze or destroy the nervous or muscular action of the parts concerned. The patient thinking himself cured, has an exalted opinion of the physician's skill; but, unfortunately, in a few weeks or months the symptoms reappear with increased severity—application is made to the same physician and with similar results, and he becomes a permanent customer of the physician,—always curing but never cured; or else, finally, after trying several other medical men with no better success, he loses all confidence in educated physicians, and, like a “drowning man catching at straws,” flies to charlatans and advertised nostrums, with a faint hope that probably some one of these may

prove more serviceable. In the last stages of chronic disease, when no cure is to be expected, and also when the patient is much annoyed, or suffers severely from some one or more severe symptoms, palliative measures, to lessen his sufferings and to smooth his passage to the grave, are justifiable; but in no other instance.

No chronic disease can be cured by the administration of remedies for symptoms only; these may be palliated, but, nevertheless, the disease steadily progresses in its inroads upon the constitution, and will continue to do so until the palliating measures cease any longer to be of service, and then the symptoms will prove faithful indices, manifesting whether or not our medicines are effecting the desired salutary influences. The morbid conditions alone, as far as we know and understand them, must be attacked and removed by our remedial measures; the symptoms, like the hour and minute hands of a watch, are mere indices pointing out to us the nature and severity of the disease, and the effects produced upon it by our treatment,—and it is only when they become so severe and painful as to cause much suffering or danger, that the true medical man would attempt to palliate them; if his treatment for the morbid conditions causing the symptoms is successful, these will gradually diminish in severity and finally disappear, without a recourse to palliating measures.

Chronic diseases require a considerable length of time in order to be thoroughly cured, which cure has to be effected, molecule by molecule, cell by cell, globule by globule, during the changes effected in the system from a morbid to a healthy condition. The quantity of medicine, or the length of time necessary for a cure can never be precisely or satisfactorily known at the commencement of the treatment; this depends upon several conditions and circumstances, as, the character, duration, and severity of the disease, the condition and functions of the organ or organs diseased, the extent to which the brain and nervous system is involved, the age of the patient, the degree of resisting power, and the susceptibility of the system, or of the diseased organs or tissues, to the influence of medicines. I will refer to an instance or two, which although not strictly in accordance with the facts or the true merits of the matter under consideration, will, nevertheless, tend to convey a faint idea of the absolute necessity of length of time in order to effect cures in chronic diseases. A large three-story brick house may be torn down in eight or ten days by five or six men, but the same number of men can not rebuild it in the same length of time; it must be rebuilt, brick by brick, with the intervening mortar, timbers, etc., occupying several months before its erection can be per-

fectured by the same number of workmen; so the broken-down system of months or years standing, must be rebuilt, molecule by molecule, cell by cell, etc., not only using agents to remove the morbid conditions of the fluids and solids, but likewise adopting measures to restore the functions of the various secretory, excretory, and other organs to their normal condition, as well as to impart tone and vigor to the brain and nervous system; the only advantage in the latter instance, that is, with the diseased system, being the presence and influence of vital action, which is absent in the house. Again, it is well known that brandy will intoxicate, yet no one can tell the exact quantity necessary, nor the time it will require to intoxicate any particular person or persons—this depends, the same as with medicines, upon the susceptibility of the parties to the influence of the brandy. One person may become inebriated in ten minutes from taking a wineglassful, while another will require three or four hours and a pint of liquor. So two patients, laboring under the same form of chronic disease, may pursue the same treatment—one will become permanently cured in three months, the other not until twelve or eighteen months of treatment have passed.

Chronic diseases of a similar character, and of six or seven years duration, may, with some patients require only three months for a cure, while with others, one, two, or three years may be necessary. Young, active persons can be more readily cured than individuals of advanced years; after fifty years of age, permanent cures are rarely effected, yet such patients can be materially benefited, so as to enjoy life, and even have it prolonged, by the adoption of the proper measures.

But there is one thing to which I would most earnestly call the attention of the physician, and which is of immense importance to his reputation, as well as to his patient's recovery, and that is to use in practice none but the purest and best medicines, whether extracts, tinctures, syrups, concentrated preparations, powders, or chemical principles. The difference in price between a superior and an inferior medicine not being generally known by the practitioner, he is apt to prefer the latter presuming that it may answer his purpose. Thus, a worthless article of rhubarb or of extract of belladonna, may be procured for fifty or sixty cents per pound, while a superior article of either will cost two dollars and upward per pound; the practitioner, looking only at the name of the article, its price, and the fee he will be likely to obtain from his patient, purchases the cheapest article; it fails to benefit his patient, and, forthwith, he attributes his insuccess not to the in-

feriority of his medicine, but to the fact that it is not suitable for the case. But this is not all, producing no desirable results from his inferior purchases, his patient applies to another medical man, who, if he employs good and pure articles, effects a cure, and perhaps with the very same remedy which failed with the first attendant, the last agent used being, however, of superior excellence. If physicians desire success, they should not hesitate, in all cases to obtain the very best medicines, and, if they are costly, the patient must pay the cost, if he desires health. Better to give up the patient entirely than to tinker with his health by means of cheap and inferior drugs. I have known inferior and cheap articles of jalap, rhubarb, etc., to have been given to patients for months with about as much benefit as they would have derived from the same quantity of sawdust. Procure good medicines or none at all; then, if the patient will not pay for them, dismiss him—for he is neither of service to himself nor to his medical attendant. It should be the pride and ambition of the physician to keep the very best of articles on hand; his reputation, and his success depend upon it.

In the *examination* of chronic disease, the physician should adopt some systematic plan, not only to aid in arriving at a correct diagnosis, but also to facilitate the investigation, and, at the same time, have no organ neglected. Many medical men after hearing a patient's statement, prescribe for him at once without any further examination, or perhaps they may ask a question or two in an indifferent manner; this is wrong, and betrays either indifference to the patient's welfare, or an ignorance of the subject or disease. Some ask a number of questions, but in such an irregular, random-like way, as to elicit no useful information, frequently bewildering the patient, as well as confusing their own ideas. Others, again, adopt the plan of interrogating by systems, confining their questions first to one system, say the Circulatory; then to another, the Respiratory; then to the Nervous; the Digestive; Genito-Urinary, and Integumentary. This last is a very excellent method, by means of which the physician ascertains all the derangements of one system before he approaches those of another, and then, from the aggregate symptoms, their character, severity, etc., he will be enabled to form a more positive and certain diagnosis, and arrive at a more correct mode of treatment. The Nervous System embraces the brain, spinal cord and nerves. The Circulatory System includes the heart, arteries, veins, and capillary blood-vessels. The Respiratory System includes the nares, the larynx, trachea, and lungs. The Digestive System comprises the mouth, tongue,

tonsils, fauces, pharynx, œsophagus, stomach, abdomen, liver, spleen, large and small intestines and peritoneum. The Genito-Urinary System embraces the kidneys, bladder, scrotum, testes, urethra, vagina, uterus, ovaries, and mammæ. The Integumentary System comprises the whole of the skin including the scalp.

Besides these, it will sometimes be necessary to examine in regard to the muscles, diaphragm, bones, eyes, ears, etc.

The course I generally pursue is, firstly—to listen to the patient's statement of symptoms,—secondly, to examine the different systems referred to above—thirdly, to ascertain as far as possible all the previous history of the case, as well as the patient's antecedents, *i. e.*, habits, previous sicknesses, injuries, exposures, business, health of parents, etc.

Several things are included in an examination besides mere questions and answers; as, 1, *inspection* of parts by the naked eye, with the aid of a speculum, or with a magnifying lens; the countenance, the chest, the abdomen, the eyes, the ears, the throat, the vagina, the uterus, the skin, etc., are the parts to be inspected, as to their normal or abnormal conditions; 2, *palpation*, which includes passing the tips of the fingers gently over a part, or making more or less deep pressure, and is designed to learn the seat of pain, the presence of tumors, fluids, or any alteration in form, size, density, and elasticity of an organ or tissue, mobility of parts, etc.; 3, *mensuration*, which is principally used in diseases of the chest, to ascertain any variations in size or circumference between similar points on opposite sides of the body, as well as to determine the extent of respiratory movements; 4, *percussion*, by which we may determine the condition of certain internal organs from the character of sound elicited; 5, *auscultation*, by which we may ascertain the condition of certain internal organs from the character of sound conveyed to the ear, either with or without the aid of a stethoscope. The lungs, heart, and arteries are the organs more commonly auscultated; and sometimes the abdomen, to determine the condition of pregnancy, etc.; 6, *chemical tests*, for the purpose of detecting albumen, bile, sugar, etc., in the urine; to detect poisons in the stomach or other organs, etc.; 7, *microscopic examination*, especially in obscure or obstinate cases, from which we may learn by an examination of the deposits in the urine, whether the kidneys, ureters, bladder, etc., are diseased; whether spermatorrhea is present; whether, from the appearance of portions of soft tumors, ulcers, fluid discharges, etc., placed under this instrument, certain affections are malignant or not, as well as the character of the expectoration, of uterine and vaginal discharges, etc. To enter

into a detailed account of all these methods of examination is not within the scope of the present work; they are thoroughly described in other works of easy access, and only demand a brief reference here; some of them, however, will be considered hereafter.

In the treatment of chronic diseases, it must be remembered that nature has given several outlets, through which disease or matters not wanted in the system are carried off; and that, from this cause, (the effete and morbid matters being constantly eliminated through the skin, kidneys, bowels, and lungs), a disease may remain in the system a long time before manifesting itself,—coming on slowly, the patient being made aware of its presence only when a solid becomes attacked—and this length of time will depend upon the activity of these several organs, their condition as to health, and the nature of the disease, varying from a few weeks to several years.

It must also be recollected that there are two great systems of membranes, which are designed to separate and envelop other organs, to absorb or secrete certain fluids, and which materially differ in their structure and vital properties; these are the mucous membranes or tissues, and the serous membranes or tissues, including the skin.

In a state of health, as a general rule, the secretions from the skin and serous membranes are of an acid character, and become alkaline only from the presence of disease; while, on the other hand, the secretions from mucous membranes are alkaline, and become acid only in consequence of disease.—One writer observes,—“Serous membranes are supplied by a set of vessels distinct from those of the organs they inclose. This is an important pathological fact, because the affection of a viscus is not a necessary consequence of that of its investing membrane, and vice versa. It serves also as a grand distinctive feature between serous and mucous membranes.”

Another medical writer states,—“The posterior spinal nerves are connected with and terminate in the serous membranes or serous surfaces of the body, organs, and limbs, including those of the skin and fascia of the muscles, and are the media of sensation.

“While the anterior motor nerves are connected with and terminate in the mucous membranes or mucous surfaces, including those of the fascia of the muscles, the bronchia, and the alimentary canal, and are the media only of the forces which produce motion.

“Insensibility in the mucous surfaces is as necessary to the maintenance of animal life, as sensibility is in the serous surfaces.

The most intense inflammation of the mucous surfaces produces no pain, without an extension of the disease to the serous surfaces,—and their apparent sensibility is the consequence of the papillary lymphatic glands which rise from the serous membranes,—conspicuously through them in some places, for the purposes of sensation,—as, in the tongue, nose, and genital organs.”

As a general rule, medicines which exert sanative influences upon the diseased mucous tissue of one organ, as, for instance, the eye, will similarly influence unhealthy mucous tissues in other parts of the system, as, the throat, nose, stomach, kidneys, bladder, urethra, etc. While, on the other hand, medicines which healthily influence a diseased serous tissue of one part, will, in like manner, effect diseased serous tissues of other parts. By bearing this rule in mind, it will materially aid the practitioner in successfully treating chronic diseases, for, with a few exceptions, in which the articles act upon both mucous and serous tissues, as is the case, for instance, with the *cimicifuga racemosa*, it will be found that medicines solely confine their remedial action either to one or the other of these tissues.

It must also be recollected, that if the blood be unhealthy, it can not impart the necessary degree of health, strength, and vitality to organs and structures dependant upon it for nutrition, and that ultimately, the brain, nerves, lungs, heart, stomach, liver, kidneys, muscles, etc., will become deranged in their several functions, which derangement continuing, will terminate in organic lesions. The especial organ or organs in which disease will predominate, depends upon the peculiar relations between these and the abnormal constituents of the blood; thus, if the blood disease be confined to those constituents necessary for the nutrition of the bone, some portion of the osseous system will suffer; if the blood constituents required for the brain or nerves are abnormal, these organs will become diseased in preference to others, etc.

On the other hand, if there be a derangement of any one or more of the organs, it will interfere to a greater or less extent with the healthy condition of the blood, in accordance with, and in proportion to, the disease in the organ or organs; thus, if the lungs be diseased, the blood will also become diseased from improper oxygenization; if the stomach be deranged, the chyme and chyle will be unhealthy, and healthy blood can not be manufactured from it; if the kidneys be deranged in function, the blood will suffer according to the amount of urea, etc., thereby retained in it; if the skin, the effete perspirable matters not being eliminated, must necessarily contaminate the blood; and so on of the

brain, nerves, liver, spleen, etc. Thus, showing that disease of the blood, and of the organs, are, as it were, inseparable.

For these reasons, in the treatment of chronic diseases, I ordinarily employ what I have termed "Constitutional Treatment," or a treatment addressed especially to the blood, or to the disease, and "Auxiliary Treatment," or that which has an especial influence upon the organs suffering, functionally or otherwise, from the disease.

The agents employed in the Constitutional Treatment are those usually termed "alteratives," which effect normal changes in disease by some method of action not yet fully understood by medical men, but which, nevertheless, are used as blood purifiers upon the same principle that Ipecacuanha is administered as an emetic, viz., observation and experience have demonstrated the results which constantly follow their employment under certain conditions; and, indeed, this may be said of almost all articles employed in the practice of medicine.

The remedies which I have found to produce the most prompt and efficacious results, are, Compound Syrup of Yellow Dock, Compound Syrup of Stillingia, Compound Syrup of Turkey Corn, Iodine Pill, Iodide of Potassium, Iodide of Ammonium, Bromide of Potassium, Bromide of Ammonium, Chloride of Gold and Soda, Tincture of Black Cohosh, etc.; and I have generally found that that alterative remedy or combination of alteratives which promptly affects the urine, effecting normal changes in it both as to quantity and quality, will prove the best adapted to the individual patient in whom its use produces such changes. Of course, whenever we know of specific remedies against any peculiar form of disease, these are to be made use of in preference to all others, as, for instance, Iodide of Potassium, in case of lead poisoning of the tissues.

In the administration of medicines for the cure of chronic disease, both as a constitutional and an auxiliary treatment, there are several points to be borne in mind by the practitioner. Thus, the treatment pursued must not only purify the blood, and impart healthy activity to organs functionally deranged, but must also give nervous energy to them, so that there will be a sound vigorous vitality of the tissues; for "it is a fact worthy of notice that whatever purifying or eliminative agents are used, a cure of any disease is rarely effected, if the vitality of the tissues is not improved or made normal by tonics, generous diet, etc.; the brain and nervous system have, as a general rule, the greatest influence

over organs in causing or removing diseases of them. As a general rule, we find persons with active, energetic, nervous powers, and healthy constitution, capable of resisting all diseases termed parasitic, zymotic, nervous, and malchemical or blood diseases, to a much greater degree than others equally as healthy in constitution, but of less vigorous nervous power."

Again, it is always advisable, when it can be done, to so compound medicines, as to be able to fulfill several indications without having recourse to a separate agent or dose for each indication,—if the agents can be combined and administered in one dose, without interfering with their actions, or producing nauseous or injurious mixtures, it should be done,—in order that the patient shall not acquire an invincible repugnance to medicines, and that the stomach may be kept in as normal a condition as possible. If the food received into the stomach is properly digested, healthy chyme and chyle are formed, from which good blood may be made, and consequently, healthy secretions, and healthy action of the body generally. But if the gastric juices be diluted by a quantity of fluid before or soon after eating, or, if the nerves of the stomach be kept in a state of irritation by the too often repeated administration of medicines, we will not only fail of producing any desirable results, but will frequently increase the severity of the symptoms of disease.

The time or hour for giving medicines, is usually an hour before or an hour after each meal. Those medicines which would be decomposed, rendered inert, or made injurious, by the action of the gastric juice, or of the elements of the food, should be given when the stomach is empty, at least an hour and a half before a meal; those which can assimilate, as it were, with the nutritive elements of the food, should be taken at a time when the action of the digestive fluids have formed the food into chyme, say, about an hour or two after a meal; and those medicines which decompose each other, forming inert, stimulating, or poisonous compounds, when received into the stomach at the same time, should be taken alternately at separate periods, and at intervals between them that will be sufficient to prevent their coming into injurious contact with each other, etc.

In all chronic diseases, attended with great acidity and feebleness of the digestive organs, as manifested by a very thick and white coat upon the tongue, the body of the organ being quite pale, we need expect no benefit whatever from constitutional or auxiliary treatment until this condition is removed; the condition of the

stomach, especially, must be corrected before any permanently beneficial results will follow the administration of, otherwise, efficacious medicines. The course I usually pursue, in these cases, and from which I have derived the greatest success, is, to prescribe the Compound Charcoal Powder, to which may be added tonics, stimulants, or sedatives, as the case may require. The use of this powder must be persisted in until the tongue assumes a more healthy appearance, after which, the administration of the other remedies will be followed by desirable results. This rule is applicable to all forms of chronic disease.

The Auxiliary Treatment will depend entirely upon certain circumstances, or conditions of organs, connected with the disease; thus, if internal organs are engorged or torpid in their action, measures must be adopted to correct this; if any of the secretions are unhealthy, they must be improved; if there is an excessive action or reaction, it must be lessened by anodynes, sedatives, etc,—remembering that we have sedatives which exert their influence more especially upon the heart, the brain, the spinal cord, or the cerebro-spinal system, etc., and which must be employed with relation to their more especial influences; if there is too much debility, measures must be pursued to give tone and support to the flagging powers; and so with other conditions, meeting every requirement that may arise, and affording to the natural vital powers of the system all the assistance at our command, and without which our real remedies will not be enabled to have any curative effect.

Disease is due to debility, seldom, if at all, to excessive strength, or hyper-vital action; yet there may be an over-excited condition of certain organs requiring sedative or soothing remedies; or, a state of depression or debility, calling for the use of stimulants or tonics; which agents should be administered in connection with the constitutional treatment; the particular agents selected depending upon the system of organs which are excited or depressed. If the debility be due to anemia, a different class of agents will be demanded from that which would be used in cases arising from weak nerves, or, typhoid conditions. A strumous tendency will need agents which would not be required in its absence; and, in patients subject to erysipelas, still another class of agents will be wanted as auxiliary remedies in the treatment of chronic diseases. And so on of other diatheses or predispositions which may be connected with any form of disease.

If the nerves are weak, tonics, nervines, relaxants, or antispasmodics, etc., will be required, as indicated by the peculiar symptoms

present. If the stomach be torpid or irritated, the agents which act more especially in a favorable manner upon this organ when in such conditions, must be used ; if the liver be torpid, or otherwise deranged, the remedies which exert their influence more particularly upon this organ must be administered, and so on of other organs, as the kidneys, bowels, brain, genital system, skin, etc., and which have been more particularly referred to in Part I. As regards the skin, it might be supposed from what has already been stated, that perspiration alone ought to be able to effect a cure in cases where a suppression of it has caused the disease ; but, it must be remembered that a mere restoration of the perspiratory functions will not, of itself, tend to establish a cure, because, in addition to the retained perspiratory matters, morbid changes have occurred in the blood, and deep-seated diseases have located in the solids, requiring the aid of other and special means of treatment, to remove the chronic disease. The hygienic measures, as diet, exercise, etc., should also be prescribed in accordance with the character of the disease, the condition of organs affected, the temperament of the patient, and other circumstances connected with the case.

“ For a physician to be successful in chronic diseases, and especially in nervous affections, he must be bright, firm, confident, and explicit ; he must show that he knows the value of every symptom, and is able to explain it without a mist of words that mean nothing ; he must prove that he knows what he has to do, that he knows how to do it, the time it will require, and the difficulties he will meet with. Such an one gains unlimited confidence ; and his voice, his face, his manners, are all of them worth many a dose of the most vivifying medicine. Without this confidence, success is extremely doubtful. The bearing of this view is not, in some points, so satisfactory as could be wished for our profession, for it would dictate that the doctor who has not the power to inspire the patient with confidence, whether in himself or his art, is bound at once to consign him to another in the same or in a different line who has the envied faculty. . . . The great point to be attained is, that the physician must be superior to the patient in every point where they come in contact, and let it be well known too. He must be able to read the truth or falsity of every new symptom ; detect and punish every attempt at imposition ; never give way while administering the cold douche, etc., until he is victorious ; his word must be law ; he must show little medical sympathy, and that of the most patronizing kind ; in fine, he must be metaphorically the strict father, and he will soon influence his patient to be the happy child. . . . The patient must not be left to himself ; his will,

though it may be obstinate, is actually weak. He requires the support of a stronger mind, and is not comfortable till he has it. So it is with the so-called hysterical people; they suffer in many a form, painful alike to themselves and to others, until some master mind teaches them unequivocally that they are under control; they are like young saplings, which require the help of a stake to keep them upright till they are strong enough to stand alone."

PART III.

CHRONIC DISEASES.

CHRONIC DISEASES OF THE NERVOUS SYSTEM.

NOTWITHSTANDING the attention which has of late years been bestowed upon the functions, diseases, etc., of the brain, spinal cord, and nerves, by many eminent physiologists, our knowledge of them is yet very imperfect. True, some certainties have been obtained, but not sufficient to enable us to make positive statements or deductions. The peculiar and manifold functions and actions of these organs, not yet fully understood, their concealed positions within bony structures, the similarity of the symptoms attending their several diseases, even when of almost opposite characters, and the intimate sympathetic relations existing between them and other organs of the body, or, in a word, the unsettled state of their anatomy, physiology, etc., have all tended to throw great difficulty in the way of arriving at facts connected with them, and have thus, as a general rule, rendered their diagnosis and treatment somewhat uncertain.

Considerable knowledge, however, has been ascertained in the pathology of these organs by recent investigations, enabling us to determine the character of many affections common to them with greater accuracy than in years past, as well as to treat them with greater chances of success. And I believe the day is not far distant, when all the mysteries and intricacies connected with them will be as well understood as with those organs which are more readily recognizable by the sight, touch, and hearing. And when that day does arrive, I firmly believe that the practice of medicine will be greatly simplified, and that, in the greater part of diseases, if not in all of them, the most successful treatment will be found that which is properly addressed, locally or generally, to the nervous system.

The *symptoms* to which diseases of the brain, etc., give rise, may be stated as follows:

A dull, heavy feeling in the head, sometimes more or less severe pain or headache; periodical headache, dizziness, noises, or ringing in the ears; obtuseness of the mental faculties; confusion of ideas, weakness or temporary loss of memory; at times dejection of spirits; thoughts of suicide; startings during sleep; bad dreams; nightmare; sleep not refreshing; a difficulty or hesitation in answering questions; an indifference to surrounding objects; querulous; a sensation of numbness or tingling at the ends of the fingers and limbs; perverted vision; seeing stars and lights; sometimes total blindness; amaurosis; dullness of hearing; deafness; sometimes the sense of hearing is morbidly acute; unhealthy condition of any of the senses; delirium; insanity; convulsions; paralysis; apoplexy; impotency; extreme nervous debility; vomiting without epigastric tenderness; occasionally slight difficulty of swallowing; rigidity of the muscles of the neck; convulsive twitchings or drawing of the head to one side; twitchings of face and arms; want of command over the lower limbs; convulsions; when one of the restiform bodies is diseased, convulsions with a drawing or curving of the body to that side; if the cerebellum is diseased, there is a want of command over the limbs, an indecision in movement, a staggering or tendency to fall forward; St. Vitus' Dance, epilepsy; when the vermiform process is effected in the median line of the cerebellum, (organ of motion), catalepsy is present.

It will be seen that many of these symptoms have been and still continue to be treated as distinct diseases, as, epilepsy, paralysis, apoplexy, etc. And, probably, this will be the better course to adopt until such time as the true character and relations of these symptoms are ascertained; many of them being present when there is disease of other organs without any apparent malady of the brain or spinal marrow. When the serous tissues of the brain, throat, nose, eyes, or ears are diseased, as, in tuberculosis, pressure upon the occipital portion of the head, upon the lateral and posterior portions of the first cervical vertebral articulation, between this articulation and the skull, and upon the submaxillary and cervical ganglia of glands beneath the jaws and in the sides of the neck, (which glands will usually be found more or less enlarged), will almost always produce more or less soreness or pain in proportion to the activity of the disease,—the pain frequently darting toward the diseased point. And by this symptom disease in these parts may frequently be determined before the patient is made aware of its presence by any other symptoms. But, in the advanced stages of disease in these and

other organs, pressure upon the several parts of the spinal column and upon the spinal nerves, will, as a general rule, occasion no tenderness or pain, and hence, will prove of no value in the examination of the latter stages of disease.

The brain may be attacked with inflammation in one or several of its parts. Various names have been applied to the affection, according to the part attacked; thus, when the substance of the brain is affected, it has been called *Phrenitis*, *Encephalitis*; when the membranes covering the brain are affected, it is termed *Meningitis*; when the Cerebrum is attacked, it is termed *Cerebritis*; when the Arachnoid membrane, *Arachnitis*; the Cerebellum, *Cerebellitis*; and when there is an effusion of serum it has been termed *Acute* or *Chronic Meningitis* or *Meningo-Cephalitis*. With our present limited knowledge it is extremely difficult to correctly determine what symptoms indicate inflammation of the substance of the brain as distinguished from that of its membranes, and these various terms, however proper they may be in describing the disease, after a post-mortem examination, tend to confuse the practitioner, and, in the present state of medicine, are really of no practical value, as the treatment of each form of inflammation is about the same. Physicians of experience are well aware that every kind of symptom has been found in every variety of cerebral disease. Hence, until the pathognomonic symptoms of the seat of the inflammatory attack are positively known, the simpler the terms used in practice, the less confusion will there be in the diagnosis and treatment.

Chronic Inflammation of the Brain among adults may present the same symptoms as are common to the acute form, though of less intensity and a more gradual progress of the disease; "it may present a diversity of symptoms according to the particular part of the brain affected; or, it may proceed in a very slow, slight, and insidious manner, and escape detection until a dangerous or fatal change has taken place. The more chronic states may follow an imperfectly cured acute attack; and the latter may suddenly supervene on the former." (*Copeland*.) More commonly, chronic inflammation of the brain exists for a shorter or longer period, presenting obscure symptoms which hardly call the attention of the patient to them, until certain decided morbid conditions have been produced, as epilepsy, paralysis, softening of the brain, abscess, tumors, etc.; and as these conditions have generally been separately treated upon by writers, I will adopt the same plan, believing it to be the best—more especially as these conditions may exist unconnected with inflammation, some of them being, likewise, independent of any primary cerebral affection whatever.

I will previously remark, however, that when, after the subsidence of an acute phrenitis, the patient is left with more or less torpor or debility of the mental powers, vertigo, headache, etc.; or with watchfulness, incapability of mental exertion, tinnitus aurium, languor, pain in the limbs, increased sensibility, and marked erethism of the brain and whole nervous system, etc., the head should be kept cool, the surface of the body be properly attended to, and the bowels kept regular without purgation, and counter-irritation should be applied to the nape of the neck, or behind the ears, etc., as Croton Oil Liniment, Compound Tar Plaster, etc. Cool Water should be applied to the head two or three times daily, and the diet should be moderate, nourishing, and easy of digestion. Abstinence from business, study, and other mental applications, as well as traveling, cheerful society, change of scenery, and gentle exercise, will all be found valuable adjuvants.

If the disease passes into the chronic form, as manifested, by obstinate headache, derangement of the mental faculties, pains or spasms of the extremities, cramps, paralysis of particular parts, etc., the above measures should be energetically and persistently pursued, together with the internal administration of Iodide of Potassium, Iodide or Bromide of Ammonium, and such other agents, tonic, nervine, diuretic, anodyne, etc., as the peculiar symptoms of each case indicate.

HYPEREMIA OF THE BRAIN.

This condition has also been termed Cephælæmia, Encephalohæmia, and Cerebral Congestion; it may exist either in the cerebrum, or cerebellum, or both. When it exists in a milder degree it is known as Cerebral Plethora or Determination of Blood to the Head, in which case, although the patient may be able to attend to his usual vocations, he is annoyed with giddiness, noises in the ears, more or less headache, appearance of sparks or objects of a red color, constant desire for sleep, and sometimes sleeplessness; with some, there will be an excitation of the moral and physical powers, intellectual activity, while with others, on the contrary, there will be mental and physical inactivity, incapability of concentration or continued attention, stiffness, twitchings, cramps, etc., of the extremities. The pulse is somewhat frequent, the temporal and carotid arteries pulsating strongly; the temperature about the head is somewhat elevated; the countenance animated or suffused, and the eyes frequently red or injected.

The *symptoms* of hyperemia vary according to its degree, and to the particular part of the brain affected by it; there may be headache, vertigo, noises in the ears, numbness of the limbs, confusion of mind, somnolency, brilliancy or watering of the eyes, more or less slowness and sluggishness in motion, sometimes motion is increased; formication in the face or limbs, either on one or both sides, redness of the countenance, violent beating of the temporal and carotid arteries, the heart, at the same time, pulsating naturally; eyes injected; sometimes epistaxis; etc. These symptoms appear and disappear at longer or shorter intervals, as, every ten or twelve hours, every week, or every three or six months, etc.

The urine is usually paler than natural, slightly acid, or neutral, and contains mucus, phosphates, sulphates, and carbonate of ammonia, in various proportions; abundant urea will be present in the last stage of the disease.

In the more severe cases, nausea, vomiting, and other gastric disorders may usher in the disease; the patient will suddenly lose all consciousness, and fall down, and while in this state of insensibility the urine and feces may be passed involuntarily, the respiration will be difficult but not stertorous; and the pulsations full, strong, and frequent. This is one form of apoplexy, which is termed by the French, *Coup de sang*, and may occasion death in a few minutes, the brain showing no other lesion than congestion. If the attack does not prove fatal, after a longer or shorter period, consciousness becomes restored rapidly or gradually, with a temporary or permanent derangement of the intellect, delirium, impairment of the senses, difficulty of speech, general or partial weakness, and, sometimes, a temporary hemiplegia. Convulsions occasionally accompany the more severe forms of the disease. These symptoms will be found to vary, and to so great an extent, as to render it impossible to account for them, with our present limited knowledge of the functions of the brain.

The disease is more common to the male than the female, and though occasionally seen previous to the thirty-fifth year, it occurs more frequently after that age.

The *causes* which may develop a plethoric, or hyperemic condition of the brain are numerous; as, exposure to sudden changes of temperature; excessive cold; the use of opium and other narcotics, as well as of alcoholic liquors; over-exertion of the mind; great and long continued mental anxiety; violent muscular efforts; turning the head to look backward; want of exercise in the open air; sedentary occupations; suppressed habitual discharges; masturbation; excessive venery; organic diseases of the heart; de-

rangement of the respiratory, circulatory, or digestive systems; as well as the causes referred to under the article *Apoplexy*.

The *morbid appearances* observed after death are, in the less severe cases, in which death is due to some other disease, augmented vascularity of the brain and its membranes, and occasionally slight serous effusion between the membranes and into the ventricles. In the more severe degrees of the affection, when fatal, considerable vascularity of the scalp and cranial bones are sometimes noticed; a bright or dark-red color will be seen in the congested portions, which will be irregular or dotted in the white substance, and uniform in the gray. The blood-vessels are filled with dark blood, both those of the brain and its membranes. The substance of the brain, when cut into, is of a deeper hue than natural; if the medullary structure be divided, it will not be so white as in the normal state, and numerous minute bloody drops rapidly form upon the cut surface. In addition to these, other morbid conditions will be met with, according to the termination of the disease, or its complication, as,—serous effusion in the ventricles, or between the membranes; extravasation of blood; hemorrhage in some part; or, softening of some portion of the brain-substance.

The *treatment*, in the milder cases, consists in cold applications to the head daily, either by affusion, sponging, or the shower bath; keeping the bowels regular; the kidneys and skin in a healthy condition as far as their functions are concerned; warmth to the inferior extremities; together with moderate exercise, attention to the diet, cheerful society, and an avoidance of all causes which may tend to produce or keep up the difficulty, as, mental exertions, stimulating drinks, sleeping too long at a time, or in the horizontal position with the head not elevated, the use of too much fluid, an exposure to too great a degree of heat or cold, etc. Traveling, sea-voyages, and change of air are beneficial in obstinate cases.

In the more severe forms of the disease, the treatment must be more active. Copious evacuations from the bowels must be procured, and for which purpose the Compound Powder of Jalap one drachm, with about ten grains of Bitartrate of Potassa, should be administered every day for several days, or until the urgent symptoms have subsided. This not only removes morbid accumulations from the bowels, but by its derivative influence, causes a determination from the brain. But when there is great constitutional debility connected with the disease, it will be improper to administer cathartics or to make use of other depletive measures, and, in such cases, the bowels must be opened by injections and

mild aperients, as, infusion of *Leptandra Virginica*, *Rheum Palmatum*, etc. Warm alkaline pediluvia, sinapisms to the feet, and along the whole course of the spinal column, repeated at frequent intervals, are also proper. If the strength and condition of the patient will admit, a Spirit Vapor Bath repeated every day or every other day, will tend materially to lessen the severity of the attack.

The Compound Tar Plaster should be applied without delay to the occiput or nape of the neck, and a discharge be kept up for several weeks, or until the disease has decidedly improved; and, to avoid the delay of twenty-four or forty-eight hours, which is required for this plaster to remove the integument, before applying it, the hair may be shaven from the parts, and then some vesicating collodion be applied. The other measures named for the milder form, cold water to the head, etc., will also be indicated, and should be more actively employed.

In all cases, as soon as the more troublesome symptoms have disappeared, or become modified, the following preparation may be given to the patient with great advantage: Take of Sulphate of Quinia one drachm, Elixir Vitriol three fluidrachms; dissolve the Quinia in the Vitriol, and then add Tincture of Aconite Root six fluidrachms, Tincture of Black Cohosh four and a half fluidounces. The dose is ten or twenty drops every hour or two in about a tablespoonful of water. If the patient be pale or anemic, it will frequently happen that full doses of a solution of Citrate of Iron in Wine will have a very happy effect. In some cases, the preparation named under Chronic Peritonitis, composed of Blue Flag, Black Cohosh, Soluble Pyrophosphate of Iron, Glycerin, Water, etc., will also be of great benefit.

The hygienic measures will be similar to those named for the milder form.—I will state here that in persons having congestive cerebral tendencies, with a more or less constant pain or soreness in the back part of the head, I have removed the difficulty by a persistent use of Solution of Bromide of Ammonium, adding, in anemic cases, three or five minims of Solution of Perchloride of Iron to each dose. The Bromide may be given in solution, each dose holding two or three grains of the salt. Cold affusions or spongings to be also made daily upon the occiput and along the spinal column.

RAMOLLISSEMENT OR SOFTENING OF THE BRAIN.

Softening of the Brain is an affection which appears to have been known only in modern times. Its nature has been a subject

of much discussion, having been attributed by some physiologists wholly to chronic or acute inflammation; while others, of equal eminence, believe that it may occasionally be induced by other causes, especially in persons of advanced age, as, by a deficient vitality of the capillary vessels and substance of the brain, occurring either primarily, or in consequence of previously excited action, as well as a diminution or loss of the vital power and cohesion of the part affected, without any inflammatory symptoms whatever,—and which view is more in accordance with the several phenomena observed.

Bennett has described six kinds of softening, each having a different origin, as follows: “1. *Exudative or Inflammatory Softening*, from exudation which is infiltrated among the elementary nervous structures; 2. *Hemorrhagic Softening*, from a mechanical breaking up of the elementary nervous structures by hemorrhagic extravasations, whether in large masses or infiltrated in small isolated points; 3. *True Fatty Softening*, from fatty degeneration of the nerve cells, independent of exudation; 4. *Serous or Dropsical Softening*, from the mere imbibition of serum, which loosens the connection between the nerve tubes and cells; 5. *Mechanical Softening*, from mechanical violence in exposing the nervous centers after death; 6. *Putrefactive Softening*, from putrefaction after death.

. The first three only occur in the living subject, and give rise to symptoms, and of these three, the pure fatty degeneration, though frequently associated with the others, has been so seldom noticed, that we are to a great extent unacquainted with its symptoms as a special lesion. As regards the last three, they have been frequently confounded by morbid anatomists with the others, and all attributed to one cause.”

Softening of the brain may occur at any part of this organ, and is commonly partial; it is more frequently observed in the gray than in the white matter, and more often in the gray matter of the convolutions than of the more central parts of the brain—it is very rarely found limited to the cortical substance, which appears to be its ordinary starting place, from whence it advances to the deeper parts of the organ. Occasionally it may be confined wholly to the central or medullary matter. The extent of the morbid change varies from a space not larger than a pea, to an involvement of the whole cerebral surface.

Softening of the brain presents no *symptoms* by which it can be accurately diagnosticated, and those which have been laid down by writers, are very irregular and erratic in their occurrence. The

disease has been divided into the *acute* and *chronic* forms, presenting symptoms as follows :

In *acute, inflammatory, or apoplectic, softening of the brain*, there is generally a fixed, local, sharp, acute pain in the head; though, in many instances, this may be absent. The mental faculties become weaker and weaker; the ideas dull or confused; the answers abrupt and quick; coma; or, the ideas may be wandering and excited, with loquacity, and frequently delirium. A numbness, a tingling, or prickling in the face or limbs may at first be observed; or a deep-seated coldness in limbs about to be, or already, paralyzed; sometimes, sensibility will be increased, there being a stiffness of the limbs, with pain, contractions, and cramps. There may also be a tremulous condition of the muscles, or tetanic contraction, or convulsions resembling epilepsy, or paralysis of one limb, or of one entire side of the body,—paralysis is the general rule in this disease. The expression of the face will be found to vary considerably; there may be a wild or wandering look with great mobility of countenance—a constant look of surprise, of indifference, of dullness, or of imbecility. The mouth may be drawn to one side, and upward; an eyebrow may be slightly elevated; or an eyelid may droop,—and these may especially occur when the patient laughs or speaks. Sometimes vomiting will be present, as well as double vision. Mucus is sometimes abundantly discharged from the eyes and mouth, varying in quantity with the variations of the other symptoms. The speech becomes altered, thick, or impossible; or meaningless sentences will be constantly uttered by the patient. The pulse is strong, full, or frequent; the countenance more or less injected, and often swollen; skin hot; more or less thirst; redness of the tongue; and retention of urine; these symptoms are more marked in the latter period of the disease. The urine will usually contain phosphates, fatty matters, purpurine, and sometimes cholesterine; it will be slightly acid, or neutral. In the latter stages urea is common.

Notwithstanding the difficulty in diagnosing cerebral softening, certain symptoms have been named by writers, by which it may be determined from hemorrhage of the brain; thus, if, after an attack of apoplexy the paralyzed limbs temporarily recover their power, or become affected with twitchings, the attack is more likely to be from softening than from hemorrhage. When there is contraction of the muscles with rigidity and slight indications of apoplexy, softening of the brain may be suspected. When there is a perversion or loss of muscular power, (common also to meningitis), and this is confined to but one side of the body, it is

a strong indication of softening. Delirium in advanced life is more common when softening is present,—meningitis being a rare disease among old persons. If, during delirium, paralysis occurs, it is an almost certain indication of softening.

Acute softening of the brain may occur at any age, and is seldom if ever cured, the patients dying in from one to thirty days after the attack; more commonly on the ninth day. Sometimes the patient survives, but labors under the chronic form.

The symptoms of *chronic or non-inflammatory softening of the brain*, are as equivocal as those of the acute form. When it follows the acute form, there is a gradual improvement of all the symptoms. The mind though not wholly restored to its original vigor gradually becomes clearer; the speech gradually improves, though not fully restored; there may also be a diminution of the paralysis,—a greater capability of using the limbs, which condition is commonly preceded, as well as accompanied, by lively, prickling sensations in the palsied parts, which are sometimes quite painful, and which are indicative of softening, especially when they occur immediately after an attack of apoplexy; if they appear at a later period they may be due to a consecutive ramolissement around a clot or hemorrhagic cavity.

When the softening is gradual and progressive, not having been preceded by the acute form, it is more commonly met with in persons of advanced years. The patients complain of uneasy sensations and numbness about the head; this is succeeded by a fixed, more or less severe pain, generally frontal, but occasionally in the occipital part, and vertigo, which occasionally causes them to fall down, or to faint. After a few weeks, months, or years, numbness of the fingers and toes is experienced, with formication, usually on one side of the body only; these will be followed by weakness of the limbs, a difficulty in grasping objects and in retaining them in the hand; and in walking, one foot is usually dragged along. Sometimes muscular contraction with rigidity attacks the hand or elbow, and may extend to the whole of one side, changing in degree from time to time, until it remains permanent. There may also be a drawing of the mouth toward the paralyzed side, with injection and half-closed condition of the corresponding eye. The mind becomes impaired from the commencement, there being a failure of the memory, and a more or less enfeebled state of the attention, perceptions, judgment, and imagination.* The patient

* Dr. Bennett states that, generally, a "true exudative cerebral softening is preceded by more or less weakness of the intellect, and more especially by slow-

presents an appearance of astonishment, dullness, or indifference, and, at a later period, will occasionally sob or weep, without any apparent cause. The sense of touch becomes greatly diminished; vision is more or less distinct, or wholly abolished; hearing is usually defective; speech becomes confused or difficult from forgetfulness of words or from a paralyzed condition of the tongue, and there is a singular monotony of the voice. The pulse is apt to be slower and feebler than natural; the skin pale; and the temperature lower than in a state of health. At an advanced period, when paralysis becomes complete, the patient answers very slowly, or, being unable to express his wants, makes painful gesticulations to convey his meaning. Coma may follow the paralysis, or the two may occur together. The mental powers as well as those of sense become entirely abolished, the ability of retaining the excretions becomes lost, marasmus occurs, with gangrene of certain parts, and the patient sinks under the most complete coma.

In the latter period of the disease there will be want of appetite, dryness of the teeth and gums; a rough, brown, blackish, chopped, or finely fissured condition of the tongue; vomitings; involuntary discharge of the excretions; labored, and then stertorous breathing; feeble, irregular, unequal, or intermittent pulse; and a pale, sunken appearance of the countenance.

Persons suffering from ramollissement of the brain commonly have as the immediate cause of death, inflammation of the brain, hemorrhage, apoplexy, pneumonia of a low, hypostatic character, or from gangrene of the skin over the sacrum or the heel, which it is almost impossible to arrest, owing to the enfeebled condition of the vital powers.

If a patient complains of a violent pain confined to one side of the head, with or without emesis, and with more or less derangement of vision, but without paralysis, these are not indicative of softening, but may be symptoms of a *tumor in the brain*. If, in addition, convulsions simulating epilepsy occur, without paralysis

ness in receiving mental impressions, or framing replies to questions, frequently combined with more or less headache, confusion of ideas, and perversion of motion. Much will depend upon the seat of the lesion, the mind being disordered most in proportion to the extent and nearness of the disease, to the hemispherical ganglion,—while motion is the more influenced, according as the central and basic parts of the brain are affected. Then it should not be forgotten that whilst a cerebral softening may occasionally lead to or be complicated with a hemorrhage, so a hemorrhage is one of the most common causes of softening.

Suddenness of attack, whether of apoplexy or palsy, is (excluding external injury) the characteristic symptom of cerebral hemorrhage."

during their intervals, and especially if the mind and speech remain normal, the probabilities would be strongly in favor of the presence of a tumor.

Recamier has stated that where there is a dissonance among the symptoms they are due to softening, and, on the other hand, where there is a consonance in the paralytic phenomena, we must conclude that a hemorrhage exists. Vertigo, loss of consciousness, and paralysis of one of the sides of the body, occurring suddenly, is indicative of hemorrhage on the side of the brain opposite to that in which the paralysis has manifested itself. The continued presence of vertigo, formication, and cramps, with gradually progressing paralysis, is indicative of softening. Yet a sudden attack of paralysis, the general sensibility, the senses, and the intellect being unimpaired, is sometimes due to ramollissement, while gradual paralysis, following precursory symptoms, may arise from sanguineous apoplexy. (*Trousseau.*)

In a clinical lecture on hemiplegia due to atrophic cerebral softening, Dr. R. B. Todd observes, that in "all cases of hemiplegia the condition of the muscles of the paralyzed limbs should be noted. The forearm should be flexed upon the arm, or the thigh upon the leg, and any resistance to these movements offered by the muscles of the parts, as well as the degree of resistance, should be carefully ascertained. Sometimes the biceps will be the only muscle to oppose any resistance, at other times the triceps alone; while, with others, again, all the muscles of the limb will be in a state of intense rigidity. These different states of the paralyzed muscles,—flaccidity, slight resistance, or absolute rigidity,—are indications of different states of the brain. The perfectly flaccid condition of the muscles of the paralyzed limbs is indicative of a cerebral lesion distinctly atrophic in its nature—a lesion *the very opposite of inflammatory*, of a low kind, one in which there is a tendency to waste, and in which the vital powers are *below par*.

"The resistive state of the paralyzed muscles shows that the cerebral lesion, whatever it be, is of an irritative kind. A very frequent cause of this state of muscles is a small apoplectic clot with laceration by the effused blood of some of the healthy brain-substance immediately adjoining it. When the palsied muscles are hard and rigid, and almost in a tetanic condition, the brain lesion is of a more distinctly and decidedly irritative kind than in the last-mentioned class of cases, in which there is merely simple resistance, and is sometimes of an inflammatory nature."

Atrophic or *white softening*, he believes to be "seated in some part of the *center of volition*—that part of the brain which is immedi-

ately concerned in voluntary actions, as, the corpus striatus and optic thalamus on the left side, or parts in immediate connection with these ganglia. The softening is due, for the most part, to any condition which cuts off from the brain, or from a part of the brain, the normal supply of blood, as, for instance, ligation of the carotid artery, etc., and occurs chiefly in persons of fifty years of age and upward, depending upon a gradual change which takes place to a greater or less degree in the coats of all the arteries of the body, but especially in those of the brain. This change, which is generally known under the term *atheroma*, consists in the deposition of earthy and fatty matter in the walls of the vessels, causing a degeneration of their tunics. Sometimes the deposits are confined to the larger vessels; sometimes the capillaries are diseased, and their muscular fibers have undergone fatty degeneration. The effect of these deposits is, that the capillary circulation throughout the brain becomes more or less impeded, according to the degree of disease of the vessels, and the brain-substance gradually becoming less and less perfectly nourished, passes into a softened state, and at length melts down. The solution of continuity of nerve fibers which thus occurs, results in the effectual cutting off of all communication between the center of volition and the opposite half of the body, and induces a state of hemiplegia. . . . It is in cases of this kind that true apoplexy most frequently occurs—that is to say, in which blood in greater or less quantity becomes effused into the brain—and the blood thus poured out often plows up the surrounding nervous substance, so as to form a considerable cavity, in which the clot is contained.”

We may determine this apoplectic condition from simple softening, because, even a very small clot will almost invariably induce more or less of a lethargic or comatose condition, accompanied with more or less snoring. “In white softening causing hemiplegia, though the patient may for some time after the stroke be unconscious, lethargic, and inclined to gape, yet there will be no prolonged loss of consciousness, and the intellect will generally recover itself perfectly.”

“If blood be effused into the brain, provided it enroaches on and more or less lacerates healthy brain, then there will be more or less resistance or rigidity of the palsied muscles; while if the clot be large the symptoms of coma will be very decided and prolonged—the patient will lie in a heavy sleep, from which he can be roused only with great difficulty, or, perhaps, not at all. On the other hand, a patient laboring under hemiplegia from simple white softening, will generally be found speaking, able to answer questions

readily and rationally, although in some cases the speech may be 'thick,' according to the extent to which certain muscles of articulation and deglutition may have been affected, or to which the center of emotion may have been involved either by shock or actual disease."

He says again: "It often happens in cases of hemiplegia, dependent on white softening, that the patient recovers perfectly from the first attack, and, after a longer or shorter interval, gets another stroke of palsy; and this second seizure is rarely on the same side as the first. The reason of this appears to be, that the affection depends upon a diseased state of the blood-vessels, and that this last morbid condition is the result of a symmetrical process affecting both sides of the brain alike, but as it does not generally proceed exactly *pari passu* on the two sides, it is usually found in a slightly more advanced stage on one than on the other."

The *morbid anatomy* of cerebral ramollissement presents the following conditions: the softening itself may exist in various degrees from the natural consistence of the brain-substance to that of thin cream. In its minor degrees it may be wholly overlooked, and can be recognized only when it is touched. In a more advanced degree it is distinguishable by the sight, as, the parts affected by it, especially the optic thalami, the corpora striata, and convolutions, sink down or become flattened by their own weight. In a still further advanced degree, the affected brain-substance is wholly disorganized and in a fluid condition which may be poured out. The softened part varies in color; it may be of the normal color of the brain-substance; it may be colorless; dull milky-white or brilliantly so; or it may present various shades of redness, from a rosy pink to an orange or deep red; mahogany brown; light or dark gray, etc. The color is more or less deeper than natural, or of a rose tint, as a general thing, when the softening is the result of inflammatory action; and it contains more or less pus infiltrated through the softened tissues. If the softening extends much beyond the redness, or the effused blood, or, if the redness occupies several portions only of the softened brain-substance, we may presume that the blood was extravasated subsequently to, and in consequence of, the softening. But when the redness can be traced for some distance beyond the softened part, the softening may be considered as the result of inflammation; and the same opinion may be held when a hardened, uniformly reddish cerebral substance is observed around the softened and disorganized pulp.

The softening may be confined to one part, or it may exist in several parts, or even both hemispheres of the brain may be affected

with it. The more generally affected parts are, the optic thalami, the striated bodies and adjacent parts, the eminences in the interior of the digitated cavities of the lateral ventricles, the commissures of the hemispheres, etc.

According to Dr. Bennett, the use of the microscope is an absolute necessity in determining the true character of ramollissement, and which will detect in inflammatory softening, in addition to the normal tubular and glandular structure, exudation granules and granule cells, in various stages of development, coating the vessels, or floating loose, either isolated or in the form of masses. The more pultaceous and diffuent the softening, the more numerous are the granules and cells, and the more disorganized are the nervous tubes and normal structures. In hemorrhagic softening, the nervous tubes are broken down, the blood coagulates, forming a solid mass, with the softened nerve tissue surrounding it, presenting circular, oval, or irregularly-formed globules with double outlines, being fragments of the nervous tubes. The serum is more or less tinged with coloring matter, infiltrated to a greater or less distance, and absorbed. No granule cells are seen except at a later period as the result of exudation from the cerebral vessels surrounding the clot. Hematine in various forms and tints, granules, granular masses, crystals of hematinine or melanine, and colloid degenerations of various colors and shades, will also be present in greater or less number. In true fatty softening the vessels are not necessarily coated with granular exudation, but the nerve cells undergo fatty degeneration, primarily, enlarge, and many of them are dissolved, leaving triangular or crescentic-shaped granular masses between the nerve tubes; in addition to which the cerebral density is diminished, and the nerve tubes are easily separated and broken up.

The *treatment* of both the acute and chronic forms of softening of the brain has to be based on general principles, as there are no positive methods by which this affection can be accurately diagnosed.

When, from the character of the presenting symptoms, the chronic form is strongly suspected as existing, great care must be taken to avoid all debilitating measures. Rubefacients should be daily applied along the whole length of the spinal column and to the extremities, the bowels should be kept regular, but not purged; the kidneys should also be kept in a normal condition, being careful in the paralytic cases to learn the condition of the bladder, daily; and the whole surface of the body should be bathed every day with a tepid, weak alkaline and stimulating solution, drying with friction. Internal medication should be of a tonic character,

as, Wine and Ferro-citrate of Quinia in rather large doses; Bordeaux, Claret, Rhine, or still Catawba Wines may be employed, avoiding the Wine, however, if it exerts a rapid, or strong action on the brain. Or, the following may be given with advantage in many instances: take of Sulphate of Quinia thirty grains, dissolve in Elixir of Vitriol one fluidrachm and a half, and then add Tincture of Black Cohosh two fluidounces and two fluidrachms, Tincture of Aconite Root three fluidrachms. The dose of this is from ten to twenty drops in a tablespoonful of water, to be repeated every three or four hours. From the effects of Bromide of Ammonium upon the system, causing absorption of fat and arresting atheromatous changes, this salt may be given in conjunction with the preceding tincture, as follows: take of Bromide of Ammonium two drachms, Distilled Water seven and a half fluidounces, Solution of Perchloride of Iron four fluidrachms; mix. The dose is one fluidrachm, to be repeated three times daily.

The diet should be moderate, nourishing, easy of digestion, of a character agreeable to the stomach, calculated to improve the condition of the blood, enriching it with highly vitalized fibrin and albumen, and should not exert any positive action on the brain. Meats boiled or broiled should be used in preference to vegetables—of the latter, the succulent, the non-saccharine, and non-amylaceous are to be preferred. All articles containing much fat, as well as fermented liquors, must be avoided; the lean parts of meats only should be eaten. All excesses are dangerous. Change of air, traveling, cheerful companions, agreeable amusements, will be of great service, when these are not associated with any undue mental excitement. Active or violent exercise, strong emotions or passions, close study, watching, continued or exciting mental applications, sexual excitement, coition, and sudden exposures to changes of temperature, should all be avoided. The clothes should not be too tight, so as to interfere with the circulation, or favor cerebral congestion; and, in sleeping, the head should be somewhat elevated. A temperate situation is to be preferred to one either cold or warm.

Softening of the brain is frequently associated with cardiac, renal, or hepatic disease, either as a cause, or merely coexistent and aggravating the brain affection, and requiring the appropriate treatment for such disease. (*See Treatment of Apoplexy.*)

INDURATION OF THE BRAIN.

Induration or Hardening of the Brain is not so common an affection as softening. Three degrees of hardening have been described by writers, of which, the first is due to inflammatory action of the brain and its membranes, occurring either as a primary disease, or as a complication in some other acute affection. While the second and third degrees are considered a chronic malady, due to chronic or morbid irritation. The induration may affect the whole brain, involving all its functions and energies, in which case the chances of prolonged life are much less than when only a circumscribed portion of this organ is affected.

The *symptoms* of more general cerebral hardness, are, a greater or less confusion of ideas, a gradual loss of memory, mental derangement, followed by continuous insanity; as the affection advances in degree or in extent, there will be a complete loss of the mental faculties or dementia. When the induration is partial the symptoms will vary according to the extent of the disease and its location; there will be a gradual loss of memory, headache, difficulty of expressing ideas, want of mental concentrativeness, indifference to surrounding circumstances and events, confusion of ideas, muscular weakness, and gradual loss of the social, moral, and animal passions. Ultimately the difficulty of speech increases, paralysis, convulsions, epilepsy, or loss of muscular power comes on, with dementia, general or partial emaciation, and death. The disease is sometimes associated with induration of the spinal marrow, giving rise to a gradually progressive paralysis. Cerebral hardening is not easily *diagnosed*, as there are no pathognomonic symptoms; and although an unfavorable disease, yet the chances of cure, especially with partial induration, are supposed, by some physiologists, to be greater than those of softening. The symptoms often continue for many weeks, then remit, and are again aggravated by paroxysms. Pains often exist at the extremities of peripheral nerves, or along their course. And cases occur in which there may be no suspicion of the hardening, until its presence has been established by dissection. The palsy is generally double-sided, commencing in the inferior extremities, and advancing upward.

Morbid anatomy reveals, in the first degree of induration, a condition resembling in consistence, portions of brain which have been macerated for some time in weak nitric acid; it is also often vascular and injected. The hardening is more manifest in the white than in the gray substance, especially in the central medul-

lary parts, and less manifest in the cortical structure and convolutions; it may affect the cerebro-spinal axis either wholly or partially.

In the second degree, the hardness has the consistence of cheese, and exposed to the fire becomes hard like horn, evolves a powerful odor, and leaves behind a dense blackish residue. The horny hardness is also imparted to it by the action of nitric acid.

The third degree is of waxy consistence or like the boiled white of egg, and contains but little blood, though it is sometimes possessed of considerable elasticity, resembling fibro-cartilage.

When there is only a partial hardness, it is more commonly found in the central parts of the brain, and, at times, in the convolutions, though any portion of the organ may be affected. It is frequently observed around old sanguineous effusions, as well as around other morbid conditions of the brain-substance.

The *treatment* of induration of the brain must be based upon general principles, administering remedies according to the symptoms or indications present. Of course, the treatment will vary considerably, when the induration is attended with hyperemia of the brain, from that pursued when there is an anemic condition of this organ. By keeping the stomach and bowels free from disorder, preserving regular action of the bowels, kidneys, skin, and lungs, preventing too great a determination of blood to the head, light nourishment, traveling, and cheerful society, together with the internal use of Iodide of Potassium, or Iodide of Ammonium, etc., much benefit may result. The Compound Tar Plaster applied over the sub-occipital portion of the head, and a discharge maintained for a long time, will be found of utility in those cases where it does not cause too much depression or debility.

CHRONIC MENINGITIS.

Chronic Meningitis, or Inflammation of the Meninges of the Brain, is a disease occasionally met with among adults. It may be present as a primary disease, or it may follow the acute form. The disease is more frequently met with among males than females, and those who are subject to insanity appear to be more liable to it, though it may be *caused* by strong emotions, immoderate use of alcoholic drinks, and masturbation.

The disease is usually met with after the thirtieth year of age, although it has been observed as early as at twenty. Its progress is slow, continuing from one to ten or twelve years; it may, how-

ever, terminate sooner from some peculiar exciting causes, which render it more active.

When the disease exists as a primary one, the early *symptoms* are those of cerebral hyperemia, with constant headache, sluggishness, both of body and mind, with more or less derangement of the intellect, sullenness, great irritability, and irregularity in the movements. Sometimes there will be more or less vomiting, epileptoid attacks, obstinate constipation, perhaps deafness, as well as an impairment of one or more of the other senses. After a longer or shorter time, the ideas become confused, the speech embarrassed, progressive delirium, difficulty in moving, although there is more or less desire for motion, the muscles twitch involuntarily, and finally the intellect becomes destroyed, an incapacity to move, and, in many cases, either partial or general paralysis. Sometimes the intellectual and locomotive powers remain undisturbed, until the disease has considerably advanced. In the last stage, in addition to the above, there will be an atrophied condition of the muscles, derangement of the nutritive system, gradual emaciation, irritation of the pulmonary tubes, and colliquative diarrhea. When the disease attacks children, as the result of blows, etc., there will frequently be, what are termed, inward convulsions, each attack being attended with an extensive and semi-rigid condition of the extremities, the eyes will remain half closed and perfectly passive to external objects, a mucoid film will form over both eyes, and which is a symptom of diminished nervous influence.

The *morbid appearances* observed after death are principally seated in the pia mater, the arachnoid, and the gray substance of the brain. There will be redness, effusion of blood, etc., in the pia mater, thickening, opacity of the arachnoid, effusion of serous, or sero-albuminous fluids, adhesions in various parts from the formation of false membranes, and occasionally morbid depositions of osseous, cartilaginous, or other matters. If the disease be complicated with apoplexy, softening, or active inflammation, the post-mortem will reveal their existence.

The *treatment* of chronic meningitis will be similar to that named for Induration of the Brain, on page 166; and, although we may not be enabled to remove the disease, its progress may be checked, and the patient's life be thereby prolonged.

CHRONIC TUBERCULAR MENINGITIS.

This affection, also known by the names *Chronic Hydrocephalus*, *Hydrocephalus Internus*, etc., is more commonly met with among children from birth and upward; sometimes it has been observed in adults. It frequently occurs before birth, causing the death of the fœtus. It is, however, of less frequent occurrence than the acute form of the disease.

Chronic Tubercular Meningitis may be due to some malformation or defective development of the organs comprising the brain, during fetal life; or, to some peculiarly-inherited constitution, especially rachitic, or scrofulous. The diseases of the mother, as well as strong, unhealthy mental emotions or passions, during pregnancy, also the advanced age of the father, drunkenness, etc., have all been supposed to exert an influence upon the fœtus in producing this disease. Likewise, tight-lacing during pregnancy, great debility of either parents from excessive masturbation, or from strumous disease.

Among the exciting causes have been named improper hygiene of the infant, cold, blows, falls, disordered or difficult dentition, especially when connected with derangements of the digestive functions, tumors of the brain, tubercles of the arachnoid, chronic inflammation of the membranes, severe and exhausting diseases of the abdominal or thoracic viscera, etc.

The *symptoms* vary somewhat according to the variety of the disease. The most common variety is that in which there is an increase in the size of the head, and which occurs only when the sutures and fontanelles are imperfectly united, the rapidity of the augmentation being greater when these are not united at all, or very slightly so. In another variety, which is congenital, the head appears lessened in size, is of canonical shape, and depressed laterally and anteriorly; the infants manifest no symptom of sense or intellect, and generally die in convulsions, soon after birth, or, they may live for a few years. A third variety, is that in which from perfect ossification and union of the sutures and fontanelles, there is hardly any enlargement of the head to be observed.

The more usual symptoms observed are, irritability of temper, great nervous excitability, brilliant appearance of the eyes, suffused countenance, eyes injected and acutely sensible to light, contraction of the pupils, morbidly acute hearing, dryness and itching of the nose, in the commencing stage, followed by headache, drowsiness, stupor, heaviness of the head, dullness of mind, irregular or voracious

cious appetite, inactivity, vertigo, pale countenance, with a look of bewilderment and confused intellect, grinding of the teeth during sleep, sudden starts during sleep, and when awakened the child frequently utters a piercing scream. The skin is generally natural, the pulse quick, and sometimes there will be slight convulsions occurring occasionally from the commencement. For a time, respiration, circulation, and digestion continue unchanged; but they soon become affected, the appetite diminishes, as well as the heat and moisture of the skin; the breathing is labored and difficult; the countenance becomes pale; constipation is obstinate; the urine diminishes in quantity; and emaciation occurs more or less rapidly. The limbs become debilitated, the walk uncertain and trembling, requiring assistance until, from atrophy of the muscles, the child becomes unable to walk; the head is seldom carried erect but is inclined to one side. Vomiting is very common among children. There is comparatively but little heat of the skin, and the pulse is quick, but in the latter stage the pulse becomes weak and small, with diminution of the heat of the skin.

In infants, owing to the separation of the sutures, the enlargement of the head commences soon and proceeds rapidly; but even when the sutures are ossified, this enlargement has been known to take place to a certain extent. This increase of size is confined to the vault of the cranium only, the base remaining unchanged.—The urine will be variable in color, quantity, and in alkalinity or acidity; it will contain phosphates, tubercular matter, albumen, cholesterine, cystine, etc.

As the disease progresses all the organs of sense become more or less affected, the pupils dilate, vision is frequently abolished, there is more or less strabismus, the hand is frequently raised to the head, the intellect becomes destroyed, with delirium, idiotcy, stupor, indifference, and coma. Frequently, convulsions take place, followed by paralysis, and causing difficulty in swallowing, retention of urine, or involuntary evacuations. The extremities become cold, damp, and œdematous.

The duration of this disease is very variable; it may prove fatal in a few days or weeks, especially during infancy; and cases are on record where the patients have lived twenty, thirty, and even fifty years. But these last favorable cases are extremely rare.

It is very difficult or almost impossible to *distinguish* the first two periods of this disease, that is, the period of tubercular deposition, and that of inflammation, during life; but the last or hydrocephalic stage is more readily recognized. When this latter condition occurs we have a difficulty of standing or balancing, an unsteadiness

of the voluntary muscles, or a loss of motion and sensation in the limbs, inclination of the head to one side, blindness, with an apparent projection of the eyeballs, and more or less complete stupor. As long as these symptoms are absent there is no cause for despair; even coma is not necessarily a fatal symptom, as it may occur independently of effusion.

Painful contractions of the cervical muscles is a constant and very characteristic symptom, and is no doubt to be attributed to the irritation of the nerves at the base of the brain. To ascertain the presence of this symptom, the patient's head should be moved from side to side, watching at the same time the expression of his countenance. In some instances these spasmodic contractions extend to various parts of the trunk, giving rise to tetanic or epileptic convulsions.

M. Trousseau has pointed out a sign in this disease, which he considers diagnostic, and which he has named the *cerebral* or *meningitic mark* or *stain*. It is the appearance of a peculiar red or raspberry-colored line or mark, remaining upon the skin of the forehead, or of the abdomen, after the finger has been drawn across it. It may also be observed upon the skin of the face or neck by the pressure or irritation of other substances, as, of the bedclothes, dress, etc. This spot or mark appears to be more commonly observed in the last stage or stage of effusion; it has also occasionally been observed in other diseases, but is more common in hydrocephalus.

Chronic tubercular meningitis may be determined from the *gastric* and *remittent fever* of children, if any fever be present, by the absence of remissions, the gradual increase of the cerebral symptoms, and the absence of the "meningitic mark."

Morbid anatomy shows the cranial vault considerably expanded, more anteriorly and laterally than posteriorly; the base of the cranium remaining unchanged. The sutures are more or less widely separated, and the bones feel loose. Generally, the cranial bones will be thin, weak, flexible, semi-transparent, and more like parchment, porous, and the osseous fibers imperfect, radiated, and visible. Within the cavity of the cranium will be found a quantity of serum varying from an ounce or two to ten or twelve pounds; this fluid is generally effused in the ventricles, and but seldom in the general cavity of the arachnoid. The fluid may, according to Breschet, be contained between the dura mater and the cranium; between the dura mater and the arachnoid; in the cavity of the arachnoid; in the ventricles; or in the laminae of the pia mater. It will also be found in the spinal canal.

When much fluid is effused into the ventricles, the brain will be distended, its convolutions unfolded, and some difficulty will be

experienced in distinguishing its peculiar structure. Sometimes the corpus callosum will be found raised nearly to the skull, and thinned; the septum lucidum torn; the lateral ventricles communicating freely with the third, and this with the fourth, forming one cavity; and the nerves atrophied or softened. The cerebellum is seldom materially altered. But few morbid changes will be observed in the membranes; it is rare that the dura mater is altered, though, in some cases, the falx cerebri is absent. The arachnoid is occasionally whitish, opaque, infiltrated with serum, and, in some places, thickened. The pia mater is not destroyed, but is excessively thin, and small tubercular depositions will be observed in it. Small cysts are often contained in the choroid plexus; and the corpora striata and the thalami optici are small and compressed. Depositions of tuberculous lymph will almost always be found in the fissure of Sylvius.

As a general rule when tubercles are found in the membranes of the brain, even in the most minute proportions, they will also be found in the other cavities.

The *treatment* of this disease presents the following indications,—to overcome cerebral irritation in the earlier stages, when present; to prevent effusion into the ventricles; to excite the absorbents to remove effusion, when it has taken place; and, in every stage of the disease, to palliate urgent symptoms, and give tone to the general system, with a view to the removal or suspension of tubercular depositions. Unfortunately, much good is seldom accomplished in these cases, by treatment; yet, patients have been cured, and, according to many authors, the disease is susceptible of cure in a very great number of cases, hence, it is always advisable to attempt a cure by the judicious management of remedies.

The use of hydragogue cathartics, diuretics, and sudorifics, will prove of great utility in the first and second stages of this disease, aided by the internal exhibition of Solution of Iodide of Potassium, or Solution of Iodide of Ammonium, either alone or in combination with the Chloride of Gold and Soda. The head should be shaved, and afterward rubbed with an Ointment of Iodide of Ammonium, repeating the application two or three times every day; sometimes, advantage will be found from the addition of Extract of Stramonium to the ointment. A flannel or oil-silk cap should be worn constantly upon the shaven scalp. At the same time a discharge should be kept up from the nape of the neck, as long as the patient can bear it, by means of the Compound Tar Plaster.

The diet should be nutritious, but not stimulating; the surface of the body should be bathed frequently, and stimulating applica-

tions be applied along the spinal column, and the whole of the inferior extremities; the urinary organs should be kept as normal as possible; and gentle exercise be permitted in the open air, when this can be done. The patients should not be subjected to harsh usage, nor be made to task their brains in the least with study, and all measures calculated to irritate or wound their sensitiveness must be avoided. Above all things, no blows about the head should be permitted. Their sleep should be limited to about ten hours of the twenty-four, and instead of feather-beds they should lie upon those constructed of cotton, hair, etc.

As a hydragogue I have frequently derived benefit from the following: Take of Elaterium four grains, Alcohol a fluidounce, Nitric Acid six drops; mix. The dose is from five to ten drops in water, for a child a year or two old, and which may be repeated if necessary.

“From a belief that effusion might be the result of want of firm resistance by the unossified cranium, compression has been tried, and has proved successful in a number of instances, and in others has brought on convulsions. To produce any good effect, the compression must be gradually increased, and continued for a considerable time, loosening the bandages if symptoms of compression appear, or removing them if the skin be irritated.

“Puncturing of the cranium has occasionally proved successful, and in so hopeless a disease, when all other means have failed, we are justified in having recourse to an operation which has even occasionally saved life. In performing the operation, a fine lancet-shaped trocar is to be passed in the coronal suture perpendicularly to the surface, through the scalp and membranes, about an inch and a half below the anterior fontanelle, so as to avoid the sinus if possible, and the great veins. The fluid should be allowed to escape very slowly, the head being gently compressed in proportion, and the whole fluid should not be evacuated at once, only a few ounces at a time, and due pressure should be maintained both during and after the escape of the fluid. If the pulse becomes weak, the pupils contract, or the child faints, remove the canula and administer a stimulant,—if inflammation arise treat accordingly.” (*Churchill*.)

Dr. Conquest states: “I have now tapped nineteen cases, and of these ten were living when last heard of. Several of the children before the operation were reduced to the most deplorable condition, having frequent convulsions, with loss of sight, emaciation, etc.; but the diminution or disappearance of the symptoms has been very remarkable.” He adds, however:—“In no instance has clearly marked congenital disease been benefited, and those cases have

done best in which effusion manifestly resulted from inflammatory action, and in which cerebral excitement follows the operation ”

Dr. Watson states that the above two mechanical measures “are opposite measures and adapted to opposite conditions of the brain, the one supplying a defect of pressure, and the other relieving its excess; and that the application of either requires a clear and cool judgment and a constant attention to the symptoms which may arise during the treatment employed.” The internal medication with the iodides should not be omitted, when these last operative means are employed, unless contra-indicated.

ANEMIA OF THE BRAIN.

This is a disease which may be mistaken for hydrocephalus, and has, consequently, been termed, *spurious hydrocephalus*. It is due to a deficiency of blood in the brain, as well as a deficiency of red particles in this fluid. It may also be produced by long continued exhausting diseases, profuse hemorrhages, and whatever will impoverish the blood, or materially lessen its supply to the brain. It is occasionally met with among adults, but is much more frequent among children, with whom it is often the result of improper or imperfect feeding, protracted diarrhea, exhausting treatment, etc.

The *symptoms* of this disease, as, dilated pupils, palpitation of the heart, dyspnœa, coma, convulsions, etc., so closely resemble those that are induced by hyperemia, that it is of considerable importance to distinguish between their causes. The symptoms usually observed are, paleness of the face, the cheeks being cool or cold; heaviness of the head; languor; drowsiness, the child lying half asleep, with the eyelids half closed, the pupils dilated and motionless, the eyes not noticing any object placed before them; irregular and suspirious breathing; the feet and legs cold; clinching of the hands, or spasms of the fingers and toes; and, if the child be cutting teeth, there may be squinting, with partial convulsions, and rough or metallic inspirations. At the commencement of the disease, the tongue will be found white, the pulse quick and feeble, scanty urine, perhaps a dry, hacking cough and mucous diarrhea, and more or less emaciation, and increased irritability; these are followed by the symptoms named above, the pulse continuing weak and frequent. Coma comes on after a longer or shorter time, and death soon ensues. The urine is usually pale, slightly acid, of low specific gravity, and is deficient in urea and uric acid.

We may *determine* anemia of the brain from an opposite condi-

tion of this organ by the drowsiness, the unwillingness of the child to raise its head, the languor, the cool or cold condition of the skin, the feeble, quick pulse, and the absence of all febrile symptoms. In very young children the unclosed anterior fontanelle will be concave or natural, in anemia; while in a plethoric or hyperemic condition of the brain it will be prominent and convex.

The *morbid appearances* are paleness or less vascularity of the brain and membranes, and especially of the gray substance. More or less effused fluid may be found in the ventricles, or at the surface and base of the brain, and which may have occurred either just before or after death. The blood will be found deficient in red globules.

The *treatment* for an adult, or child of advanced years, will be gently stimulating and nourishing, as, for instance, Elixir of Cinchona and Iron, together with a moderate use of tender, properly cooked meats. At the same time making use of means to check any exhausting discharges, or causes of irritation that may be present. The sedative influence of opiates has been found very beneficial in removing symptoms occasioned by loss of blood; hence, Powdered Opium, a Pill of Opium, or Sulphate of Morphia, may be given in a rather larger dose than under ordinary circumstances, so as to occasion a prompt sedative effect.

With very young children, nourishment should promptly be given them, of a character in accordance with their age, as, breast milk, cow's milk, or goat's milk, together with ten or twelve drops of the Aromatic Spirit of Ammonia, in a little water or milk, to be repeated every three or four hours; or arrow-root with a few drops of brandy or wine in it; gum-arabic water with ether, etc., may also be administered. The limbs should be rubbed well, and be kept warm in flannel; the child should be placed in a horizontal position, and not be raised upright; small quantities of nourishing diet should be cautiously given from time to time; any irritation from dentition should be removed as soon as possible; and means taken to promptly restrain diarrhea, when it is present.

Other morbid conditions of the brain are occasionally met with, which it is extremely difficult, if not impossible to diagnosticate, which present analogous symptoms, and which are seldom benefited by treatment, as, *scrofulous, scirrhus, carcinomatous, fatty and encysted tumors, membranous adhesions, ossific and carbonaceous deposits, infiltrations of pus, abscess of the brain, cerebral hypertrophy*, as well as *atrophy, tubercles*, etc.; this reference is all that is necessary to these diseases, which are very equivocal in their symptoms and susceptibility to therapeutical measures, and can be positively

known to exist only by post-mortem examinations. All these affections, on account of the obscurity of diagnosis, and our want of correct knowledge concerning their origin and progress, require to be treated upon general principles, meeting the various symptoms as they arise, and keeping the patient constantly under the influence of solvents, alteratives, and tonics, together with the proper attention to hygiene.

Certain other conditions of the brain, giving rise to symptoms usually treated upon as diseases, as cerebral hemorrhage, etc., will be referred to under the heads of Apoplexy, Paralysis, Epilepsy, etc.

CHRONIC SPINAL MENINGITIS.

Chronic Inflammation of the Membranes of the Spinal Cord may occur as a primary affection, ultimately assuming a more active form, or, it may follow the acute form. It is frequently connected with chronic cerebral meningitis, as well as with more or less irritation or chronic inflammation of the cord itself.

The disease comes on very gradually, sometimes, existing for several years before much complaint is made; it is also frequently mistaken for some other malady, as many of the symptoms, and especially the more severe ones, are seated at distant points. Thus, it may be mistaken for weakness of the limbs, neuralgia, rheumatism, spinal irritation, chorea, etc. There is more or less tendency to an extension of the disease, both upward and downward; and, in feeble habits the disease progresses more rapidly than with the more robust, and passes much sooner into the acute state.

It may be *caused* by sedentary habits, want of exercise in the open air, intense mental application, improper, insufficient, or unwholesome food, and the various causes which determine spinal affections generally. However, among the more ordinary causes, are, injuries to the spinal column, from sprains, bruises, falls, blows, tight-lacing, etc.; sudden exposures to cold; abuse of alcoholic drinks; sleeping in cold or damp places; rheumatic disease; congestion of the membranes occurring in the course of certain fevers; sexual excesses; and especially self-pollution.

The *symptoms* of chronic spinal meningitis are numerous and varied, according to the seat and extent of the disease. At first an aching and more or less severe pain will be complained of in some part of the spinal column, which extends into the limbs, or nervous extremities in relation with the affected part; percussion over the affected part will increase the pain, but mere pressure will not;

more or less numbness of the inferior extremities, with sensations of tinglings, prickings, burnings, formication, etc. The pain may be continuous, remittent, or intermittent, and will often be increased by certain movements, or when the limbs or body are made to assume certain positions. After a longer or shorter period motion becomes uncertain and difficult, the patient often walking as if inebriated, and when the disease has extended to the superior portions of the cord, there will be likewise, a slow, irregular, jerking, vacillating motion of the arms and fingers, and which condition may continue for even several years. In connection with these symptoms there will be more or less derangement of the digestive organs, variable appetite, flatulency, constipation, or great alvine irregularity, together with a dry state of the skin, or some other disorder of its functions, incontinence of urine, the urine generally containing considerable phosphates, and, perhaps, a small amount of pus: The speech is generally affected; sometimes there will be a strabismus; and, especially in very severe cases, the mind will become more or less deranged. The pulse is, at first, not much affected, especially when the disease is confined to the inferior parts of the spinal cord; but in the later stages it becomes frequent, small, and irregular. When the superior parts of the cord are attacked, the pulse is commonly slow, at first, with more or less derangement of the action of the heart.

Finally, swallowing becomes difficult; the breathing becomes slow or irregular; more or less violent spasms of the muscles of the neck and back occur; rigidity or tetanic contraction; and these occur in the superior extremities when the dorsal or cervical parts of the cord are affected. A sense of constriction occurs, especially in the neck, back, and abdomen; suffocative feelings; paraplegia or general paralysis; coolness of the surface, emaciation, delirium, and coma. Or the disease may assume an acute form, and involve the base of the brain. Sometimes there will be no convulsions whatever, nor any paralysis.—These are the ordinary symptoms, which will be found to vary in number, in the order of their occurrence, in their intensity, etc.

Morbid anatomy reveals an effusion of coagulable lymph on the arachnoid of the dura mater, between this and the visceral layer of the arachnoid, and, sometimes, a coating of purulent matter will lie between the cord and its membranes, being more abundant at some parts than others. The lymph between the membranes may sometimes be partially converted into adipose matter, presenting a quantity of oil-globules. In some cases, there will be more or less vascularity of the cord and medulla oblongata, with effused lymph

and a turbid serum surrounding them. Occasionally the substance of the cord will be found softer than natural, and, at some part, separated into filaments. Adhesions between the membranes are also frequently met with. Thickening, induration, false membranes, cartilaginous, and ossific deposits, tubercles, tumors, etc., have all been observed on different occasions.

Discrimination. In chronic spinal meningitis the pain is more severe than in *chronic myelitis*, and extends more or less along the whole spinal column; and is but little, if any, aggravated by pressure. The disease has a greater tendency to extend itself, while chronic myelitis is confined to only one part of the cord; in meningitis the muscles of the back are contracted, from a mere rigid state to a violent spasm amounting to perfect opisthotonos, which is not the case in myelitis. In meningitis the pressure of the effused lymph upon the cord and roots of the nerves may cause paralysis, but sensibility continues; in myelitis not only is motion lost or impaired, but sensibility also. When both meningitis and myelitis are present, the discrimination will be much more difficult.

Chronic inflammation of the membranes of the spinal cord is a serious disease, sometimes progressing slowly for a number of years, at other times, rapidly passing into the acute form, and which may happen at almost any period during its course. The most favorable period for its treatment is before paralysis has occurred; after this, although a cure is seldom obtained, it may be considerably benefited by proper management. Much, however, will depend upon the cause of the disease, the constitution and habits of the patient, the complications of the disease, etc. When complicated with cerebral meningitis, or chronic myelitis, the chances for recovery are less favorable.

The *treatment* of chronic spinal meningitis consists in keeping the bowels, stomach, skin, and kidneys regular, making use of light nourishment, avoiding all sources of irritation, preserving cheerfulness, and affording the spinal column as much rest as possible, never fatiguing it, or augmenting the pain by exercise, or by remaining too long in an upright position. In addition to this, the Iodide of Potassium, or Iodide of Ammonium, should be used internally, as well as Oil of Turpentine, which has a powerful tendency to prevent lymph from being effused from these membranes. The whole length of the spinal column, as well as the inferior extremities, should be rubbed two or three times a day with the following liniment: Take of Oil of Amber one fluidounce, Tincture of Arnica two fluidounces, Oil of Turpentine six fluidounces; mix. Dry cupping

along the spinal column, frequently repeated, will be found useful in the commencement of the affection, but after it has somewhat advanced, the Compound Tar Plaster applied over the painful parts, and a constant discharge kept up therefrom will be found superior to anything else, except in those cases where it causes too much depression of the vital force, or debility, under which circumstances it should be applied intermittingly. To overcome the pain in chronic spinal meningitis, when very severe, the following will be found a very efficacious preparation: Take of Sulphate of Quinia two drachms, Elixir of Vitriol six fluidrachms, dissolve the Quinia, and then add Tincture of Aconite one and a half fluidounces, Tincture of Black Cohosh nine fluidounces; mix. The dose is from ten to twenty drops in a tablespoonful of water; to be repeated every hour or two for three or four months in succession. In some cases a combination of Tinctures of Aconite and Gelseminum will be found advantageous. The measures here indicated should be perseveringly persisted in for a number of months. (*See Treatment of Chronic Myelitis.*)

CHRONIC MYELITIS.

Chronic Inflammation of the Spinal Cord may exist as a primary disease, becoming more or less acute and rapidly fatal, or, it may follow the acute form. It is sometimes complicated with chronic spinal meningitis, as well as other affections of the cord or its membranes. The disease, when not the result of the acute form, usually comes on very slowly, and, when of limited extent, may remain for years before presenting any serious symptoms, or, may even terminate favorably. The disease is not so apt to extend itself as is the case with chronic spinal meningitis.

The *symptoms** vary considerably, according to the part affected,

* Dr. C. E. Brown-Sequard gives the following list of symptoms as characterizing chronic inflammation of the middle or lower parts of the dorsal regions of the spinal cord, attended with paralysis of the lower limbs of long standing:—
 "1. A constant pain at the part of the spine corresponding with the upper limit of the inflammation of the cord.—2. Whether a constant pain exists in a marked degree or not, pressure upon the spinous process of the vertebræ, (sometimes even a slight one), when made at the upper limit of the inflammation, almost always causes an acute pain.—3. A sponge filled with warm water and passed along the spinal column, gives a normal sensation of heat in all the parts above the seat of the inflammation, but a burning sensation at its upper limit.—4. A small lump of ice passed along the spinal column gives the natural sensation of cold everywhere, except at the level of the inflammation, where it produces a burning sensation.—5. In all cases of myelitis there is a sensation as if

the extent of the disease, its complications, etc. The more common symptoms are, more or less continuous or intermittent pains, or a dull, heavy sensation, or a feeling of soreness, experienced in the head, and more commonly in the occipital portion; these will vary in severity at different times, becoming more painful as the disease progresses. There will also be more or less pain in some part of the spinal cord, together with pains or cramps in the corresponding muscles or limbs. The pain in the head will frequently dart down to the neck and along the back, in various erratic ways, and the muscles of the neck are apt to be more or less painful and rigid, which conditions are much increased by motion. The pain in the back may exist at any part, though more generally located in the dorsal vertebræ, and is not only aggravated by movements of the

there were a cord, or other ligature around the body, at the limit of the paralysis; in some cases it is very slight. It is chiefly due to cramp of some part of the thoracic or abdominal muscles.—6. Sensations of pricking by pins and needles, formication, of burning or intense cold in the feet, legs and thighs, and sometimes in the abdominal walls. These are important indications of myelitis, and, although referred to the parts affected, are due to irritation of the gray matter of the spinal cord; they exist with as much severity, if not more, in parts deprived of sensibility, as in parts which are still sensitive.—7. Cramps in the feet or calf of the legs are frequent, with all patients, as well as in the large muscles of the abdomen. A cramp limited to one part, and continuing for several days, may form a kind of lump, which may be mistaken for a tumor.—8. Whether myelitis exists only in a small zone of the spinal cord, or occupies the whole of the dorso-lumbar enlargement, the paralysis of motion exists in all the parts of the body that receive their nerves from the portions of the spinal cord that are below the upper level of the inflammation. The degree of paralysis varies in different patients, but it is nearly the same in the various muscles in the lower limbs in the same patient.—9. When the lower part of the dorsal region of the cord is attacked, paralysis of the bladder and of the sphincter ani is almost always present; when the seat of the inflammation is higher up in the the dorsal region, there is rather a spasm than a paralysis in the sphincters of the bladder and anus. There is then often a retention of urine, owing to the paralysis of the bladder while the sphincter vesicæ is more or less in a spasmodic state.—10. The urine is always alkaline, or, should it become acid from the use of certain articles of food, the alkalinity will soon reappear.—11. Anæsthesia, or at least a diminution of sensibility, always exists in myelitis, except when the gray substance is not the seat of the disease, which is very rare. Usually, the inflammation begins in the central part of the gray substance, and then a diminution of sensibility is one of the first symptoms. That peculiar kind of muscular sensibility which serves to direct our movements is especially impaired in the very beginning.—12. When the dorso-lumbar enlargement is inflamed, reflex movements can hardly be excited in the lower limbs, and frequently it is impossible to excite any. On the contrary, energetic reflex movements can always be excited when the disease is in the middle of the dorsal region, or higher up."

body and limbs, but, also, in most cases, by pressure or percussion made over the seat of the pain, and by the application of a sponge wet with hot water upon the part. In connection with these symptoms, there will exist, according to the duration and extent of the affection, more or less derangement of the digestive organs; pale tongue coated with a thick white fur; impaired or morbid appetite; nausea; vomiting; costiveness; sometimes a deranged condition of the urinary organs, with more or less irritation at and around the neck of the bladder; sometimes presenting symptoms resembling those of stone in the bladder; the urine irregular, turbid, generally alkaline, and containing sulphates and phosphates; if the disease is seated in the lower part of the spinal cord, retention of urine, impotency, or even priapism may take place; the skin is often very sensitive to the touch; if the upper portion of the medulla is affected, there will be more or less disorder of the respiration; deglutition may be more or less difficult; and hiccough may be present; in most cases, sleep will be disturbed and unrefreshing; there will be a feverish, irritable mental condition, with despondency; a sense of weariness and an indisposition to move about; the slightest exertion produces considerable fatigue, with, sometimes, tremblings of the inferior limbs, and a peculiar feeling of weakness, especially at the knee; the mind is apt to wander, or become occasionally confused; memory is more or less impaired; mental concentration becomes difficult; and various other strange and unaccountable symptoms, many of them similar to those named under Spinal Irritation, and which are often confounded with rheumatism, neuralgia, laryngitis, hysteria, deranged intellect, hypochondria, monomania, etc.

After a time, there will be a numbness in the fingers and toes, or in the limbs, with formication; and sensibility, as well as the power of motion, gradually diminishes. These symptoms may be the first experienced,—those named above not having been observed, or only in a very slight degree. The numbness slowly advances; tremors occur; motion becomes vacillating and unsteady; spasms or cramps in one or several parts occur every now and then; involuntary startings of the muscles; paralysis and great diminution, if not entire loss of sensibility. The pulse, not affected at first, becomes slow or irregular, and feeble; the temperature of the surface diminishes; the body gradually emaciates; the limbs become wasted, flabby, cold, with œdema; sloughs form on parts which undergo continued pressure; dyspnoea, coma, and death either from exhaustion or asphyxia. In some cases the speech will be inarticulate; the voice may be lost; the heart's action will be irregular; the chest will feel constricted, and the abdomen, as if a

cord were tied round it; and, sometimes, there will be convulsions instead of paralysis, or the paralysis may follow the convulsions. Various hypotheses have been advanced for the diversity and multiplicity of the symptoms, but, as nothing positive has been advanced except in a few of them, it is deemed unnecessary to state them here; they would be more in place in a work on physiology and pathology of the brain and nervous system. The same *causes* that produce chronic spinal meningitis may also give rise to chronic myelitis. It may also follow spinal apoplexy when this is not fatal.

The *morbid appearances* are softening of the cord, suppuration, or induration; the softening is often yellowish, or in the more acute cases, slightly red or pinkish. Either one or more columns may be affected; and the morbid change may be confined to the white structure only, or to the gray, or it may involve both. The gray substance is more frequently affected. Softening, however, is more common with the acute form of the disease, and induration with the chronic; the hardening being more common to the white columns. The whole spinal marrow may be involved, and even the brain; but, more generally, the disease is located only at the cervical, dorsal, or lumbar portions, or, at two or more of these points at the same time. More commonly the spinal membranes will also be found involved to a greater or less extent.

The *discrimination* of this disease from *chronic spinal meningitis*, has already been named on page 177; it, as well as the spinal meningitis, may be determined from *rheumatism* or *neuralgia*, by observing that these diseases are unaccompanied by spasms, cramps, tonic contractions of the muscles of the back, numbness or prickings in the extremities, girding or constriction of the chest or abdomen, loss of sensibility, palsy, stupor, etc. In *spinal apoplexy*, the symptoms come on suddenly, with rapid paralysis and loss of sensibility.

The *prognosis* of chronic myelitis is more favorable in its early period than subsequently; though, it is often the case that the early stages may pass unnoticed, and the patient becomes aware of his disease only when too late for a cure. Chronic myelitis develops itself and advances toward its termination very slowly; in its early periods, it is susceptible of improvement, or even a perfect cure, provided the cord is free from any positive injury. The less severe and numerous the symptoms the more favorable is the case. When paralysis has occurred; when there is a persistent failure in the strength of the system; when the urine contains a great degree of abnormal elements; when, from loss of power over the sphincters

the excretions pass away involuntarily; or, when from continued pressure upon certain parts of the body, sloughs form,—these are unfavorable symptoms. The prognosis is also more unfavorable when the disease is located in the cervical or dorsal portions of the spinal cord, than when it is confined to the lumbar region. (See note on page 178.)

In the *treatment* of this disease, it should always be borne in mind, that when the symptoms indicate an active condition of it, the measures pursued should be entirely to overcome this active condition, and during which period, the remedies hereafter named should not be employed. But, as soon as the more active symptoms have been removed, the disease being, as it were, in a passive condition, then the measures hereafter recommended may be pursued. These consist in an employment of the remedies, etc., advised in the treatment of chronic spinal meningitis, aided by the internal use of Phosphorus, Ergot,* Arnica, Belladonna, Electro-Magnetism, Black Cohosh, douches of tepid or cold water, rest in the horizontal position, and perfect quietude of the mind. Great care should be taken that the bladder be emptied at proper periods, and in relation to this matter, the chronist† should personally ascertain the condition of this organ from time to time, especially in the more advanced stages. In this disease, coition must absolutely be prohibited, as well as sexual excitements.

Dr. C. E. Brown-Sequard has stated that from experiments instituted by him, he believes that Ergot and Belladonna diminish the quantity of blood in the spinal cord; while, on the other hand, Strychnia and Brucia increase it. The application of cold to the spinal column, produces a contraction of blood-vessels by a reflex action, but if this action be very powerful, it will be followed by exhaustion and dilatation of the blood-vessels, and an actual increase of the amount of blood circulated in the cord. Lying upon the back, with the arms, head, and legs upon high pillows, favors a determination of blood, or temporary congestion in the spinal cord; while, on the contrary, lying upon the abdomen, or upon one side of the body, with the limbs on a lower level than that of the spine favors a diminution of blood in the spinal cord, or a partially anemic condition of it. Therefore, as myelitis is accompanied by an increase of blood in the spinal cord, he advises the following

* Or, its active constituent, *Ecbolina* (Wenzell) or *Ergotina* may be used; the first in doses of $\frac{1}{20}$ th of a grain gradually increased to $\frac{1}{16}$ th; the latter in doses of from $\frac{1}{4}$ of a grain to a grain; either, to be repeated twice a day.

† A physician who treats chronic diseases only.

treatment: The patient must keep in a horizontal position, so as to give rest to the spinal cord, but he must avoid those positions of the body in which by gravitation the amount of blood in the cord will be increased; hence, he must never lie on the back. Dry cupping daily on the various parts of the spinal column will prove of service. A plaster of Extract of Belladonna, at least four inches wide by six inches long, should be worn for several weeks upon the back, over the painful portion of the spinal column. Internally, Powdered Ergot is to be administered twice a day, in doses of two or three grains, gradually increasing the dose to six or even eight grains twice a day. If no amelioration of the symptoms occur after a few weeks of this treatment, the Extract of Belladonna should be given twice a day in doses of a quarter of a grain. If after two or three months treatment, the patient gets no better, the Iodide of Potassium should be given, in addition to the above, in doses of five or six grains twice a day. If chronic spinal meningitis is suspected together with the myelitis, the treatment should be at once commenced with the Iodide of Potassium, and the Ergot and Belladonna.

SPINAL IRRITATION.

By this term is meant pain or tenderness in some part of the spinal column, either with or without pressure, not being accompanied by symptoms of fever, inflammation, injury, or organic lesion of the several parts belonging to the vertebral system. It is a disease which has given rise to considerable discussion among medical men, and the true character of which is not yet positively determined. The affection has been called *Rhachialgia*, also "functional disorder of the spinal marrow." It is frequently connected with a chronic functional disease of some one or more organs of the body, with which it stands related, either as cause, or effect by reflex action; and it is a well-known fact that many of these chronic affections can be detected, located, and, of course, their ordinary symptoms be described, merely by ascertaining at what parts of the spinal column pressure causes tenderness, soreness, or severe pain—the activity or intensity of the disease detected in the organs being generally in proportion to the degree of soreness or pain produced by the pressure, as well as to the degree of pressure required to occasion the pain, etc. The pressure is to be made upon the spinous processes, and upon the ganglions of the spinal nerves in the intervertebral spaces on each side of the column. If the original disease be in the organ, as, the liver, kid-

neys, or heart, etc., the pain on pressure will be experienced at that portion of the spinal column from which the diseased organ receives its supply of sensitive nervous force; because, if an organ is diseased, it can not receive or normally dispose of its supply of nerve-force; thus, deficient action must, to a greater or less extent, derange the perfect normal condition of its nerve-center, from which must result more or less irritation. But if the disease has its commencement in the sympathetic ganglia or spinal cord, then there will be more or less derangement of the organs in correspondence with the diseased or irritated portions of the spinal column,—because, a healthy supply of nerve-force can not be distributed to an organ whose nervous center is in a state of irritation, no matter from what cause.

Writers have generally considered that tenderness on pressure at some portion of the spinal column is an attendant on many neuralgic and hysteric affections; this is true,—but, it will frequently be found to exist as an attendant on functional lesions not accompanied by neuralgia or hysteria, and will often be found absent when these two maladies are present. The pain caused on pressure, when co-existent with diseased organs, is seldom present when their lesion is organic, and especially, when it is in its latter stages. In all maladies presented to the practitioner, he should invariably examine the condition of the spinal column, as to pain or tenderness on pressure,—because, whether this exists as a cause or an effect, its presence will be found in many instances to materially interfere with the efficacy of treatment; while on the other hand, its diminution or removal will be followed by speedy benefit to the affected organs under treatment.

Spinal irritation may arise from various *causes*, as, excessive labor, exposures to sudden changes of temperature, sprains, sudden muscular efforts, injuries to the spinal column, masturbation, excessive sexual intercourse, prolonged lactation, mental anxiety, too frequent child-bearing, intemperance, excessive sedentariness in a sitting and stooping position, etc.; it may also arise from uterine disorder, disease of any of the organs of the body, worms, piles, anemia, rheumatic or neuralgic diseases, intestinal irritation, etc., or, on the contrary, instead of being caused by these affections, it may even give rise to most of them. In many instances it will be almost, if not quite, impossible to attribute the irritation to any positive cause.

The *symptoms* of spinal irritation are, more or less tenderness, soreness, or pain, at one or more portions of the spinal column, and which may be constantly or remittingly present without pres-

sure being made; or which, may only be experienced when the thumb is made to press more or less firmly on the parts heretofore named. Sometimes, the pain will be very intense upon the slightest pressure, frequently darting inwardly toward affected organs, often aggravating or exciting unpleasant symptoms in them, which entirely disappear only after a night's rest; while, at other times, considerable pressure will only excite a dull sensation of tenderness at the part compressed. Between which two conditions there will be a multiplicity of modifications.

In connection with this symptom, will be associated many others, due to lesions of internal organs, which are more or less numerous and severe, according to the severity of the affection and its complications, and the characters of which are in accordance with the location of the spinal irritation and the functions of the corresponding affected organ or organs. Thus, we will have symptoms of gastric, or hepatic disease, when the pain is in the dorsal region; of uterine disease when it is in the lumbar; of renal disease, when between the dorsal and lumbar; of lung or heart disease, when in the cervical portion, and so on, or, several of these may be associated together. In addition to these, there may likewise be symptoms of neuralgia, hysteria, rheumatism, etc., more or less pain when lying upon the back, when walking, or even when merely standing erect; palpitations of the heart; sinking paroxysms; sense of suffocation; slight chills, etc. Indeed, it is unnecessary to name the numerous symptoms here, because, as already stated, they will usually be found of a character consistent with the functions and sympathies of the organs in correspondence with those portions of the spinal column which are affected.—A neglect of this spinal disease, whether it be primary or secondary, or, an improper treatment of it, may cause it to result in a chronic, and even an acute inflammation of the spinal membranes, ultimately followed by delirium, coma, and death.

The *diagnosis* of spinal irritation is generally considered an easy matter; but there are some points connected with it which are very difficult, if not impossible to determine. Thus, it is of the utmost importance to determine whether the pain produced is merely the result of an irritable condition, or, whether it is owing to inflammation or structural disease of the spinal cord or of its membranes. It is also important to determine whether the affection originated in the spinal cord, or in the diseased organs.

If the case be one of spinal irritation, without inflammatory or structural lesion, the patient will obtain relief by assuming the recumbent position; while, on the contrary, the pain in the various

organs affected, as well as in the back, will be increased by jumping, lifting heavy weights, or by placing the body in certain bent or contorted positions; there will also be a correspondence between the organs affected and the part of the spinal column at which the pain is manifest; there may be yawning or frequent paroxysms of sneezing; and, there will be no symptoms of gradually progressing loss of sensation and motion. Besides which, there will be a great disproportion between the severity of the symptoms, and the accompanying constitutional disturbance.

The determination, as to the origin of the affection, will be a difficult matter; the previous history of the case, and its symptoms, must be ascertained and carefully considered, as well as the peculiarities present at the time of the examination. The symptoms in the organs are often more severe when the disease commenced in them than otherwise; yet there are so many exceptions to this that it can not be regarded as a general or reliable rule. When our treatment for the removal of the spinal affection fails to produce any great amount of benefit, or, when with an improvement of the spinal symptoms, those of the organs continue without any amelioration, we may then believe that the organs were primarily affected.

Again, when in connection with the symptoms common to the diseased organs in correspondence with the affected part of the spinal column, there are certain symptoms unusual to them, as, prickling or tingling sensations in the skin, sinking sensations, chilly sensations along the back, sensations of suffocation, or of constriction, faintness, nervous irritability, extreme sensitiveness to changes of temperature, etc., the disease may be attributed to a spinal origin.

The *prognosis* of primary, uncomplicated spinal irritation is favorable; but when this irritation is the result of diseased organs, or occurs in connection with rheumatism, syphilis, gout, or active struma, etc., the prognosis is less favorable, and must be based upon the symptoms of the accompanying diseased organs. If the disease passes into some structural lesion of the cord, the prognosis will be still less favorable.

The exact seat and the correct nature of this disease still remains undetermined, as no opportunities for post-mortem investigations have been had, at least not until structural changes in the cord had followed the previous irritable condition.

The *treatment* to be pursued in spinal irritation, will be twofold in its object, viz.,—to remove the irritation or spinal tenderness, and to restore diseased organs to a normal condition. To fulfill

the first indication, counter-irritants must be applied over the affected parts of the spinal column, the action of which, as to severity, will vary according to the degree and activity of the disease. And among the preparations which I have found the best adapted for this purpose, are, the Compound Capsicum Liniment, the Compound Liniment of White Turpentine, or, the Compound Tincture of Camphor. Among these, I prefer the latter, which should be applied with considerable friction, and be repeated once or twice daily, so as to keep up a sense of heat or burning during the day, while the patient is moving about. Sometimes the Croton Oil Liniment will be found peculiarly beneficial; at others, Dry Cupping over the tender points will answer a most excellent purpose. The principal object is to produce an external irritation which will cause a favorable derivative influence upon the congested or irritable nervous center. As a general rule, it is only when the disease has been of long standing or is connected with inflammatory or structural lesion of the cord or its membranes, or with a neuralgic affection, that pustulation, as, by the Croton Oil Liniment, or, suppuration, as, by the Compound Tar Plaster, will be required. And the pustulation or suppuration should be allowed to heal, whenever either of them are followed by an increase of the nervous symptoms, or by severe constitutional irritation. In cases liable to be attacked by these symptoms, it will be better to make the applications over a limited surface only, at a time, changing them to another limited surface of the affected portion of the spinal column, as the first place is healing over, and thus keeping up a constant derivative action from one or other part of the backbone.

In many instances, counter-irritation will fail to effect any beneficial results, and may even aggravate the symptoms; in such cases, I have found an exactly opposite course to prove valuable. A Plaster of Belladonna, or of Stramonium, or of some other narcotic, worn over the tender points, will in these instances, afford prompt relief; and this will be found especially the case in many uterine affections, as well as in maladies of the generative organs generally, with which the spinal tenderness is apt to be associated.

Internally, I have derived benefit from the use of Belladonna, Gelseminum, Aconite, etc. But the preparation from which I have received the greatest service is composed as follows: Take of Sulphate of Quinia one drachm, Elixir Vitriol three fluidrachms; dissolve the Quinia, and then add four and a half fluidounces of Tincture of Black Cohosh, and six fluidrachms of Tincture of

Aconite Root. The dose is from fifteen to thirty drops, in a tablespoonful of water, every three hours; continuing its use persistently for three or four months. In one case where, with the spinal irritation, the patient was very sensitive to the touch in various parts, around the chest and back especially, where the slightest contact of the finger with the skin occasioned a great degree of a tickling sensation, with constipation, turbid urine, exceedingly sensitive prostate, and symptoms resembling vesical calculus, a cure was effected by the use of the following pills: Take of Sulphate of Quinia one scruple, Podophyllin eight grains, Alcoholic Extract of Nux Vomica one grain and a half, Alcoholic Extract of Black Cohosh, a sufficient quantity to form into a pill mass; mix, and divide into twenty pills, of which one was taken three times daily.

In addition to these means hygiënic measures must be rigidly attended to, especially such as relates to keeping the bowels and kidneys regular, and the skin in as normal a condition as possible; the diet should be nutritious and easy of digestion; all spirituous liquors and tobacco must be avoided; sexual indulgences prohibited; changes of temperature guarded against; violent exercise, as well as standing too long in an erect position, late hours, and all mental and physical excitement, should also be carefully avoided,—and, during the day, the patient should once or twice take rest in the recumbent position, an hour or two each time. Traveling, change of air, of scene, cheerful society, etc., will be found of great advantage.

But, although we may remove the spinal tenderness, and thus terminate for a time all the painful and unpleasant symptoms, yet, if the irritation of the organs be allowed to continue, we may reasonably apprehend their renewal on the application of slight causes; and conversely, if by appropriate means we should correct the disordered action of the organs, without at the same time relieving these irritated points, our efforts would be alike unavailing. We must, therefore, in addition to the means adopted to remove the spinal irritation, at the same time employ those measures which are indicated for the removal and cure of the accompanying lesions of organs, the most common of which are, chronic laryngitis, prolapsus uteri, menstrual derangements, renal, hepatic, and gastric disorders, dyspepsia, asthma, cough, heart-affections, rheumatism, neuralgia, syphilis, scrofula, gout, anæmia, chlorosis, hysteria, etc.,—the particular treatment of which will be found described under their respective heads.

It may be proper to state that spinal irritation has recently been

described by Dr. T. Inman, of Liverpool, as having a muscular origin, and he has attributed all affections in which pain or tenderness of the spinal column, on pressure, are prominent symptoms, to some morbid condition of the muscles rather than of the nerves—considering that the so-called spinal disorders originate most commonly in a feeble and painful affection of the muscles of the back. That there are symptoms frequently met with, strongly resembling those of spinal irritation, but which are due to the causes named by Dr. Inman, is undoubtedly a fact—but he is in error when he attributes true spinal irritation to morbid muscular irritability. That spinal irritation exists without any affection of the muscles of the back, is undoubtedly true; and, vice versa, a painful and enfeebled condition of these muscles may exist independent of any spinal irritation. As this subject, although not included in the list of Diseases of the Nervous System, will not probably find a better place in the work for its consideration than the present, I will therefore devote a few pages to it. The muscular affection is termed by Dr. Inman,—to whom I am indebted for the following description,—

MYALGIA.

This is also known by the names of “weak back,” “spinal disease,” “stiffness of the back,” “stiffness of the muscles,” “tiresomeness of the muscles,” etc. It is an affection frequently met with among both males and females, being, however, more common among the latter; and is often confounded with true spinal irritation. Sewing-women, milliners, hard-working females, writers, authors, and persons whose occupations require them to continue for a long time in one position, either erect or stooping, daily, are exceedingly liable to myalgia; and the weaker the person the greater will be the tendency to pain.

This disease is an irritable condition of the muscles which are inserted upon the spinous processes, as well as of various other muscles, and which irritability is *caused* by over-exertion, or over-straining of one or more portions of the muscular system in debilitated subjects; including, in the word muscle, tendon, fiber, or fascia, as the case may be. There is scarcely any part of the body which is absolutely free from these affections, for they are to be met with wherever there are voluntary muscles or their tendinous prolongations. Some parts are more frequently attacked than others; the trunk more commonly than the extremities; the abdominal walls oftener than the thoracic; and the legs more con-

stantly than the arms. The tendinous parts are more frequently the seat of pain than the fleshy, but when the affection is of a spasmodic nature, the fleshy parts alone are implicated.

When a healthy individual exposed to unusual and excessive muscular action, "laughs until his sides ache," while witnessing the pranks of a comic actor, it is by no means uncommon for him to feel some pain, soreness, or abdominal tenderness on the next day. Everybody is familiar with the stiffness, pain, or soreness that follows the first fencing, boxing, dancing, or other athletic lessons. The seaman remembers how his eyes have "burned" after many an hour's weary lookout for land, especially at night. The seamstress, too, often stitches till her eyes *ache* with watching her needle—*i. e.*, until the muscles that move the ball are thoroughly weary. Those who have occupied themselves for a length of time in a bent-over position, complain of pain and stiffness of the muscles of the back. As a general rule, when the sensation is referred to a tendinous part, it is spoken of as pain,—when to a fleshy part, as an ache. Now, in a feeble person, or when a long-continued strain or over-exertion is kept up with certain muscles, it will eventually result in myalgia. As long as the relation *between the work to be done and the power to do it*, remains the same, the exertion of the muscles is not *unusual*. But, *whenever muscles reduced in power are obliged to do the same work as when they were strong, the exertion they put forth is unusual, and the violence of the exertion is proportionate to the weakness of the muscles*. It costs us no suffering, while we are in good health, to walk erect, or to sit over our books and papers; but when sickness has reduced our powers, when a refractory stomach has refused the necessary supplies of food, or when we have been brought low by accidents and loss of blood, we find the exertion excessive, painful, or too great for our powers. As long as the school-girl is healthy and strong, she can sit erect for hours, and at the end feel *weary* only; but as the influence of sedentary life, mental exertion, deficient appetite and digestion, a crowded sleeping apartment, and school, begins to be felt, the weariness is changed to *painfulness*; she is no longer *fatigued*, she is suffering.

The predisposing causes, then, of these muscular affections are, a want of tone in the system, and a diminished strength in the muscles.

The *symptoms* of myalgia in some respects greatly resemble those of spinal irritation; there is more or less pain or tenderness along the spinal column, or at certain parts of it, which sometimes extends to other parts of the body, and is often increased by motion. In some cases no pains are experienced at all, excepting a soreness or

tenderness upon pressing upon the spinous processes along the spinal column,—in others, there is pain, which is aggravated by pressure at various points upon the spinal column, by bending, stooping, lifting heavy weights, etc. These pains, when extending to the body, are very variable in their character and position; sometimes they are described as aching, hot, or burning pain, in some instances as if a hot coal were at the part. At other times, instead of pain, there is a *tired* or *wearied sensation* of the affected parts. The pains are generally absent in the morning on getting up, but as the day advances they gradually appear, augmenting in severity until bedtime, when they cease or diminish considerably soon after lying down. They frequently come on suddenly, and are sometimes accompanied with spasms or cramp-like feelings. When they follow excessive exertion, they come on the first thing in the morning and gradually subside.

In connection with the above there will be other symptoms, varying with different patients, no two presenting exactly the same. These are, dizziness; tinnitus aurium; palpitation; quick, weak, or irritable pulse; a tendency to sigh frequently; a disposition to cry on the slightest occasion; a difficulty in restraining laughter; snoring during sleep, with heaviness on awakening; giddiness on getting out of bed; yawning while at the toilette; anorexia, or irregularity in appetite or digestion; torpid bowels; lithic or phosphatic urine, which speedily becomes ammoniacal; foul breath; bad taste in the mouth; headache; languor or lassitude during the day, and, perhaps, wakefulness, or nervous excitement at night. Pressing upon some portion of the spinal column will sometimes cause both pain and cough; and, in addition to the above-named symptoms, there may be loss of spirits; mental depression; a morbid appetite; vitiated taste; love of sympathy; feigning diseases; strange twitchings or jerkings and twistings of the body; dyspnoea; difficulty of swallowing; nausea after eating; optical fancies, as seeing specters, etc.; sometimes diarrhea, strange noises in the ears, etc.

Every part of the body is liable to muscular pains, but their most common seats are,—in the occipital and cervical region, occasioning more or less severe headache, the pain seeming to be prolonged from the occipital region, into the occipito-frontalis, or, causing the patient to imagine that he or she has contracted a cold in the head; in the neighborhood of the acromion process, with a sense of weariness and sometimes cramps; at the inferior extremity of the sternum; at the posterior-inferior portion of the upper arm; in the inframammary region; in the abdominal region, complained of as a “continual grasping” pain all over the abdomen, as if somebody

were drawing the patient up, and which pain becomes very severe on walking; in the sides, with tenderness on pressing upon the intercostal spaces, or "only a stitch in the side;" in the lumbar region; in the dorso-lumbar region; in the right and left hypochondria; in the pubic region; in the gluteal region; and in the inferior extremities.

The pain, in these places, is mostly referred to the insertion of the sterno-mastoid; the origin of the temporal; the occipital origin of the trapezius; the claviculo-scapular origin of the trapezius; the origin of the greater pectoral and deltoid; the ensiform cartilage; the triceps of the arm; the lower origin of the pectoral; the commencement of the linea semi-lunaris; the origins of serratus magnus and external oblique; in the origin, insertion, or along the course of the external and internal oblique, and the transversalis; in the intercostal muscles; in the rectus abdominis; the quadratus lumborum; the latissimus dorsi; the erector spinæ; the pubic insertion of the rectus; the gluteal and crural muscles; the biceps of the leg; the plantar fascia, etc.

It is of importance to form a *diagnosis* between myalgia and *spinal irritation*, the symptoms of which so closely resemble each other. Dr. Inman has given the following rules to guide us in our decision of this matter: The pains are more commonly described as hot and burning, are generally absent in the morning, but appear during the day, gradually increasing in severity until bed-time, when they cease. If they follow severe or unusual exercise, they come on the first thing in the morning, and subside gradually. The pain is referred to some muscle, or to some part where it is fibrous, and is aggravated by bringing the muscle into increased action. At first, generally, the pain is relieved by steady pressure, but after a time the pressure can not be borne, and the parts become tender to the touch. It is also relieved by relaxation, or artificial support; and, however severe it may be, the pulse remains unaffected, or is softer and weaker than natural. The pain can almost always be traced to unusual exertion in a strong person, or to a weak muscle having to do the work of a strong one; and when the patient is describing its location, he almost invariably moves the hand in the course of the fibers of the affected muscles. Cramp often comes on suddenly during the night while the patient is moving. A muscle which has been thoroughly fatigued should not become cramped until it has been rested to a greater or less extent by sleep. The cramp comes on suddenly, and is attended with apparent swelling and great hardness; the pain is severe, of variable duration, and passes off

slowly, with a vibrating, twitching, or creeping sensation, leaving more or less soreness after its disappearance. Cramp seldom comes on in a muscle until it has in some way become debilitated, and when once seized with cramp, the muscle is very liable to other similar attacks.

We must be very careful, also, to discriminate between myalgia and neuralgia, as well as diseases of internal organs, as, of the heart, lungs, liver, kidneys, bladder, intestines, uterus, etc., with which this malady is very apt to be confounded.

There have been but few opportunities for *post-mortem* investigations, but, as found to be the case with animals, we may conclude that there is paleness, atony or softness of the muscles, more or less rupture of muscular fiber, laceration of blood-vessels, and extravasation of blood between and around the broken fibers.

The *prognosis* is almost always favorable under correct treatment.

The *treatment* of myalgia consists in imparting tone and vigor to the system; allaying the pain and irritability of the affected parts; and allowing the tired, over-worn muscles a sufficient time to rest, that they may be enabled to repair fractured fibres, take up extravasated blood, and recover tone.

The strength of the system must be husbanded by diminishing the amount of labor undertaken, whether this be mental or bodily, or both. "Few persons, till they give their unbiased attention to it, have any definite idea of the amazing amount of work women get through with by day. From six or eight in the morning till nine or ten at night, they are incessantly at work: washing, dressing, scouring, carrying, cleaning, making beds, cooking, shaking carpets, sweeping floors, ironing, sewing, darning, knitting, nursing, teaching infants to walk, carrying them in their arms, etc. All these require muscular exertion, and this is sometimes excessive in degree—their very insignificance, and their daily occurrence, cause them to be ignored. The laborer, the farmer, the man of business, the doctor, know little of them, for they are performed out of their sight. They all see the rooms pretty nearly in the same condition, their linen, etc., in the proper state, and never care about, for they do not know, the trouble required even in these small details.

"A woman herself, knowing that some of her companions in sex get through their duties without suffering, imagines that the same duties can have no influence over her health or feelings, and she attributes her complaints not to what she has to do, but to something that prevents her doing them, and which may be

removed by art or skill; and as the abdominal muscles are commonly affected, the patient takes pills or other aperient medicines, and thus makes matters worse. The only way to lighten labor under these circumstances is to *insist on a rest every day* in the recumbent posture, for at least half an hour, and more, if necessary, in the middle of the day.

"It is much easier to know what must be done than to induce our patients to comply with our recommendations. For this we must be prepared. One can not take rest, for the household duties fall upon her, and she is unable to give them up, or too poor to provide a substitute. Another will continue to nurse until she is physically incapacitated,—putting, in her own estimation, present suffering against a probable future contingency, involving greater pain, and more expense. Another, (a very common occurrence), has formed her notions concerning her case from reading some newspaper paragraph, from some nurse, etc., while she has been in health. When she is in any way debilitated, she is too weak to think,—the mental labor required to take up a new train of thought, hopes, and confidence, is too great. In her own idea the patient is firm; in the opinion of the healthy lookers-on she is obstinate in her resolves, and actually prefers pain and quiet of mind to relief and mental violence."

But, it is absolutely impossible to effect a cure in this disease, unless rest be taken; lying upon the back in bed, or upon a sofa, for at least half an hour at a time, and repeating it, according to the degree of debility, one, two, or more times daily, and without any occupation of the mind in conversation, reading, writing, or other exertion. The use of an arm-chair during the day should be recommended in the more severe cases. Sleep at night must be promoted by Opium, Morphia, Infusion of Scullcap, Valerian, etc., and for immediate relief, especially to the muscles of the abdomen and extremities, they must have some rest or artificial support, by an elastic or other kind of bandage, strapping, and the like.

Change of air and scene operates in two ways; by removing the patient from exhausting labor, and by placing her or him in the most favorable condition for improving health. A change anywhere is serviceable, whenever it is attended with absence of excessive labor of body or mind, and the presence of pleasant associations and companions. Change of air is of little use when the patient carries with him all the habits, etc., of home. It is of small advantage for a worn-down mother to go to the sea-side, or elsewhere, for her own health, if she takes with her the most chargeable of her younger ones; or, for an author, editor, etc., to resort

to the country with his pens, ink, and paper, in undiminished array. Equally useless is it for the victims of hysteria to change the parties, concerts, etc., of the town, for the assemblies, balls, dinner parties, picnics, etc., of watering or country places.

Exercise, proportioned to the strength of the patient, must be taken every day *in the open air of the country*; but never to fatigue or to cause shortness of breath. But if the symptoms are aggravated, or do not mend under the exercise, it must be wholly prohibited. When exercise is advised, it must be invariably adapted to the condition of the patient, and where walking is too much, a carriage, quiet horse, or other passive exercise must be used. The diet must be ample and generous, nourishing and easy of digestion, with such intervals between the meals that, while there is sufficient time on the one hand for the stomach to rest, there is not sufficient to enfeeble it, on the other. Long fasts are injurious to the sick. When the body is exhausted by labor or illness, the stomach takes part in the debility, and is unable to digest the ordinary food employed; the want of appropriate nourishment, in its turn, increases the patient's weakness, and thus the two may go on gradually aggravating each other.

Wine alone is not strengthening, it is simply heating or stimulating, and it is given not as a substitute for food, but to assist the powers of nature. Rhine, Claret, Burgundy, Catawba, Port, Champagne, or Bordeaux wine, mixed with the yolk of an egg and a little sugar to aid in giving tone to the digestive power, is better than all the tonic medicines that can be given; but where wine can not be had, some simple tonic bitter made into a decoction, and sweetened, may be taken in tablespoonful doses three or four times a day; in some cases, tonic Wine Bitters will prove of service. If the wine gives rise to gastric acidity, a proportionate quantity of brandy and water, peach or apple brandy and water, etc., may be used instead. In anemie or very debilitated patients, a few drops of Wine of Iron, or other chalybeate preparation may be added to each dose; but it must not be made unpalatable. Tea and coffee must not be used; these are generally much craved by this class of patients, on account of the transient stimulus they impart; but this is at a great cost to the patient, ultimately. These articles are extremely prejudicial to the delicate stomach, especially when taken very hot and very strong. Milk and water, when it agrees, cocoa, or infusions of raspberry, peach, strawberry, or senlleap leaves, etc., not too hot, are much better beverages at meals. Solid food is always preferable to liquid nourishment.

Bathing the body with cool or tepid, not cold, water, by means of a sponge or otherwise is of immense value; it should be practiced every morning. Sea-bathing, or bathing with salt and water, is often serviceable. This bathing should not be carried beyond five minutes, for it is then abused and does positive harm. Sometimes the shower bath will be useful. The value of any bath is proportionate to the reaction it produces; it will improve constitutional power, but will not generate it. As to therapeutical treatment, medicines should not be given unless absolutely required. The bowels must be kept regular, but on no account must purgatives be administered.

Tonics are sometimes of service; the Tincture of Chloride of Iron, Wine of Iron, Cod Liver Oil, Hydrastis, Gentian, Colombo, Chamomile Flowers, Peruvian Bark, etc., may be employed singly, or in various combinations. The following will be found to form a pleasant and very useful tonic: Take of Sulphate of Quinia twenty grains, Sulphate of Morphia five grains, Elixir of Vitriol one fluidrachm and a half,—dissolve the two alkaloidal salts and add Tincture of Black Cohosh, Essence of Cinnamon, each, one fluid-ounce. The dose is thirty or forty drops in a tablespoonful of water, to be repeated three or four times daily. A teaspoonful of Linseed Oil and half a teaspoonful of Whisky mixed together, also forms a good tonic.

To remove the irritable condition of the muscles, local applications may be made over the painful parts, of Solutions, Plasters, or Liniments of Belladonna, Stramonium, Hyoscyamus, Conium, Morphia, etc. A Liniment of Chloroform, Camphor, Fluid Extract of Aconite Root, and Oil of Amber, of each, equal parts, will be of great value; it may be rubbed three or four times a day along the course of the spinal column, and over the painful and tired spots or muscles in other parts of the body.—When it is actually impossible for patients to take the required rest, they may find much relief, but not always a cure, from the proper employment of galvanism, which has, of itself, effected permanent cures where the patients suspended their mental and physical labors, and sought amusement and rest by change of air, scenery, etc.

Forcible extension of the affected muscles gives almost immediate relief if the cramp, which may be present, is recent; when the cramps are severe, Morphia internally and externally will be found of great benefit, as well as the measures hereafter advised under the head of Cramps. If cough, leucorrhœa, laryngitis, uterine disorder, neuralgia, diarrhea, or menorrhagia, etc., be present, treat as hereafter named under the proper head of each.

APOPLEXY.

Apoplexy is a more or less sudden loss of consciousness, feeling, and voluntary motion, with a slow, labored, and stertorous respiration; or, in other words, a rapid attack of coma from cerebral compression, more commonly the result of effused blood.

It rarely occurs in young persons, being more frequent among those of advanced years. According to Dr. Bruckner, the first year of life presents the greatest danger from this disease; it goes on diminishing till the tenth year, and increases rapidly from fifteen to twenty. From this time it increases more slowly up to forty years, when it increases rapidly. About the sixtieth year the greatest increase of danger takes place; it only increases more slowly from this time to seventy-five; from this age, the danger gradually diminishes. The ages forty-eight, fifty-eight, and sixty-six years, are peculiarly dangerous. Males are more liable to the disease than females, though the latter are still more subject to it after sixty. Mountainous places and the country are safer, as a residence for persons disposed to apoplexy, than lowlands, towns, and cities. Winter is the most dangerous periods for these persons; summer the safest. Epidemic intermittents, sudden changes of weather, catarrhal fevers, appear to increase the danger.

It has, heretofore, been the impression that middle-aged and corpulent persons with short, thick necks, florid cheeks, and good-sized heads, were alone liable to apoplexy, but this is an error; the disease equally occurs among those whose necks are long and slender, and whose countenances are naturally pale or colorless.

The *cause* of apoplexy is cerebral congestion, with or without effusion of blood or serum; from pressure on the nervous fibers; division, or fatty degeneration of the nervous-substance; want of nervous energy; unhealthy blood; forcible impulsion of blood along the cerebral blood-vessels; interrupted supply, or deficient momentum of blood in the brain-substance; and the influence of narcoties. When these are followed or accompanied by cerebral hemorrhage or extravasation of blood, then the case may prove fatal or result in paralysis. The apoplexy being due to the congestion; the fatality or paralysis to the effusion of serum or blood in the brain. So that we may have apoplexy without effusion, and effusion without apoplexy.

The predisposing causes of apoplexy or of the conditions of the brain giving rise to it ultimately, are numerous; diseases of the heart may tend to prevent a free return of venous blood from the

brain, or may impel the blood to the brain with augmented force; hypertrophy of the left ventricle of the heart, has a most direct relation to apoplexy, constituting in many cases, the immediate cause of the attack, acting, probably, by causing structural changes from the continual over-distension and straining to which the cerebral arteries are subjected by the long-continued pressure and unwonted energy with which the hypertrophied heart propels the blood along them.

Indeed, hypertrophy of the heart is a change concomitant to that period of life when apoplexy is most prevalent; the same may be said of dilatation, and valvular diseases, which impede the reflux of the blood along the veins.

Chronic renal disease, as, a small, hard, shrunken, and granular condition of the kidneys, or, on the contrary, a large, soft, and greasy-looking state, is likewise apt to be present with the cardiac affection. It is a fact almost generally admitted by physiologists that when the functions of the kidneys are interfered with by structural disease, a hypertrophied condition of the left ventricle of the heart is a most frequent and prominent accompaniment.

Plethora, inanition, or anemia, dyspepsia, gout, diseases of the minute arteries or veins, or of the capillary vessels of the brain or its membranes, a morbid condition of the blood, disease of the liver, excessive hemorrhages, muscular straining, long and intense mental application, sedentary and luxurious living, excessive venery, intemperance, exposure to extremes of temperature, a more or less constantly depressed, or irritable condition of the mind, frequent indulgence in sleep after a full meal, tight neckcloths, use of narcotics, or anything that will tend to keep up a more or less constant determination of blood to the head, or, impede the reflux of the venous blood, or, favor a plethoric condition of the cerebral capillary vessels, at the same time diminishing the vital energy of the brain, may be considered as predisposing causes.

Among the exciting causes may be named, violent exercise; excessive venereal indulgences; masturbation; intoxication; powerful mental excitement, or depression; straining at stool or while urinating; an undue distention of the stomach from eating a hearty meal, while the system is exhausted or enfeebled from any cause whatever; exposure to the heat of the sun; lifting heavy weights; sleeping after meals; tight neckcloth; violent fits of coughing or sneezing; suddenly rising from a stooping position; turning the head suddenly to one side, which gives rise to cramp or tonic spasm in the muscles of the neck, and thus impedes the free flow of blood from the head; sudden changes of temperature; constipation; large

bleedings or hemorrhages; innutritious diet, or whatever will cause an anemic state of the system; injudicious employment of the warm bath; crowded or ill-ventilated rooms; suppression of customary discharges; epilepsy; noxious vapors; prolonged watchings, etc.

The *symptoms* of an attack of apoplexy vary; more generally the attack occurs suddenly, without any appreciable premonitory symptoms, the patient falling to the ground in a state of unconsciousness, from which he cannot be aroused, with his face much flushed, tumid, and sometimes livid; his breathing slow, laborious, and stertorous; the veins of the neck and head more or less swollen; the head hot, and often in a profuse perspiration; the eyes projecting, bloodshot, half open or closed; the pupils usually dilated, but occasionally much contracted; the pulse strong, full, and regular or slow, but soon becoming weak, rapid, and unequal or intermitting; a frothy saliva is often blown from the mouth with considerable force. The attack may last from a few minutes to four or twenty hours, or even to forty or more. Sometimes the patient will be insensible and motionless for several days, gradually recovering his intellect and strength; but, more commonly, the mental powers become impaired to a greater or less extent. Frequently the first attack terminates fatally, and it is very rare indeed that the patient survives the third attack.

Some persons fall down suddenly, with an entire suspension of sense and motion, flushed face, full pulse, and a stertorous respiration; occasionally, there will be spasmodic muscular contractions, or convulsions. The apoplectic seizure may terminate fatally; or, perfect recovery may take place; or, recovery with a transient or permanent hemiplegia. The preceding varieties are due to cerebral congestion, with or without effusion of blood or serum.

Again, the patient experiences a sudden attack of pain in the head, becomes pale, faint, sick, vomits, and falls down in a state resembling syncope,—the face being pale, the body cold, and the pulse feeble, perhaps a slight convulsion may ensue. Occasionally, there will be no falling down, but a slight and transient forgetfulness. From either of these, recovery generally takes place in a few minutes, but is followed soon after, in a few hours or several days, with a sense of oppression, forgetfulness, incoherency, coma, and death. This is due to an anemic condition of the brain, to feeble circulation through its vessels, or to cerebral hemorrhage.

Another mode of attack is that in which the loss of the powers of speech and of one side of the body occurs suddenly, without stupor, or at all events any long continuance of it, from which recovery may take place, or it may pass gradually into apoplexy in a few

hours. This is probably owing to more or less cerebral effusion, the apoplectic seizure being due to pressure from the formation of a clot. Sometimes paralysis occurs before the apoplectic attack, which may not manifest itself for an indefinite period.

It is rarely the case that an attack of apoplexy comes on without some premonitory symptoms, which may, however, be so slight as to escape notice entirely. They may exist singly, or several of them may be grouped together; and, if properly attended to, the attack may be warded off, and even the tendency to it be wholly removed. These premonitory symptoms are, dull pain in the head, with a sense of weight or heaviness, the pain may be located at any part, but mostly around the occipital region; giddiness; drowsiness at unaccustomed periods; frequent attacks of nightmare; unpleasant dreams; cramps or spasmodic action in various parts of the body, mostly in the calf of the legs and in the neck, (trachelismus); lividity or redness of the countenance; pulsation of the cerebral arteries; obscurity of vision; irritability of temper, or unusual serenity or apathy of mind; epistaxis; heavy sleep with deep, stertorous respiration; transient loss of memory; slight faintness or vertigo, with paleness of countenance, and momentary disturbed intellect or oblivium; ringing in the ears; faltering in speech or using one word for another; incoherent talking; suffusion of the conjunctiva; difficulty of writing, or inability to spell the words; a pricking sensation of the extremities; unsteady or tremulous gait, etc. The most important of these symptoms are giddiness, especially on stooping, on straining at stool, on coughing, or on pulling on a tight boot, and especially when conjoined with feebleness; heavy and unrefreshing sleep, with more or less drowsiness through the day; incompetence for any continued mental exertion; cramps of the legs at night; a constant sense of fulness or weight in the head; a constant inclination to sigh; a numbness or palsy of some part; and a thick, husky condition of the voice.

The *diagnosis* of apoplexy, as a general rule, is not difficult—the sudden attack, the coma, the laborious or stertorous respiration, the relaxation or rigidity of the limbs, the entire loss of consciousness, and the slow, full pulse, indicate the character of the disease; and more especially when we procure the previous history of the person attacked. There are, however, certain conditions which may be mistaken for apoplexy. Thus, the *dead drunk* person resembles one in a state of apoplexy, which may be determined by the odor of liquor in the breath, besides, the person may be partially aroused by shouting in his ear, or by applying a strong odoriferous stimulant to his nostrils. Yet drunkenness may excite a true apoplectic fit.—

When the coma is due to *concussion of the brain*, we can only determine it by learning the history of the case or by detecting the injury done to the head. In other cases, we may determine the case not to be apoplexy, when pinching the extremities, tickling the soles of the feet, etc., partly rouse the patient.

Apoplexy may be distinguished from *epilepsy* by the absence of convulsions in the former; or, if present, they are slight, and affect only a part of the body; in epilepsy, there is usually a strong convulsive paroxysm, a foaming at the mouth, and frequently a gnashing of the teeth, and a noise somewhat resembling the barking of a dog; but there is seldom any stertorous breathing, and the limbs are not so relaxed as in apoplexy. Apoplexy is more common to middle age—epilepsy to early age, and is a chronic disease, the attacks occurring more or less frequently; the fit is also of shorter duration, and the patient more readily aroused from it. When apoplexy is caused by *narcotics*, the respiration will be more tranquil, but not stertorous, the pulse will be more rapid, the face pale and calm, and, in most cases, the patient can be aroused by violent agitation. The vascular or anemic condition of the brain, has already been referred to among the symptoms.

According to M. Prus, the symptoms of meningeal apoplexy are as follows: paralysis of motion rarely follows subarachnoid hemorrhage; in intra-arachnoid hemorrhage, it occurred in six cases out of eight; in both forms, paralysis of sensation rarely exists, and when it does, it is very slight,—somnolency and coma also exist in both forms of hemorrhage. The drawing of the mouth to one side does not occur in meningeal apoplexy. Delirium, fever, and dryness of the tongue, frequently appear in intra-arachnoid hemorrhage toward the fourth or fifth day, or at the period when the existence of a false membrane may be verified; these symptoms are not met with in subarachnoid hemorrhage. Subarachnoid hemorrhage constantly proves fatal before the ninth day. In intra-arachnoid hemorrhage the patient sometimes survives a month or longer; at times, even recovery may ensue, the blood being absorbed by the surrounding cysts.

As to the *prognosis*, although apoplexy does not always immediately terminate fatally, nevertheless, it is always to be considered a serious disease. The second and third seizures are more fatal in their character than the first, or, if recovered from, are more apt to leave permanent impairment of the mental faculties, as well as paralysis. Some patients die immediately; others again not for two or three days after the attack, or death may ensue from reaction. Genuine apoplexy almost never causes instantaneous death;

when the case terminates fatally, it is usually after a lapse of some months, from paralysis—though it occasionally proves fatal in from a few minutes to several hours. In those cases where sudden deaths occur, it is more frequently due to some disease of the heart. We may look for an unfavorable termination, when the coma is profound, continues over twenty-four hours, with frequent or intermittent pulse, contracted pupils, cold and profuse perspiration, slow, laborious and stertorous respiration, and involuntary evacuations of the bladder and rectum. Frequent yawning, after the coma has partly passed off, frequently carrying the hand to the same part of the head, or the supervention of delirium, are also unfavorable symptoms. Complete hemiplegia, without coma, the mental faculties being unimpaired, and the non-affected side being possessed of perfect motion and sensibility is more favorable than a more partial paralysis with stupor or coma. Apoplexy occurring in the insane, or with epileptics, old persons, or those of enfeebled, broken-down constitutions, or after previous paralytic attacks, is likewise unfavorable.

The supervention of a gentle, warm perspiration, pulse full and natural, respiration not stertorous, or the stertor gradually diminishing, epistaxis, free alvine and urinary discharges, with a consciousness of the evacuations, are favorable indications. In all cases, no positive prognosis should be given until after the tenth day, as a renewal of the extravasation or other unfavorable change is apt to take place on the eighth day after the attack.

The *pathological appearances* vary; sometimes the evidence of lesion is very obscure, or, not sufficient to account for the fatal attack. In most cases, however, there will be more or less vascularity of the brain-substance; at times this will be absent; extravasation of blood, either liquid or coagulated, in the latter instance often being spread out in the form of a membranous layer; the infiltrated blood may vary from a drachm to an ounce or two. Generally there will be a softening of some part of the brain; with fatty degeneration of the arteries and capillary vessels, or, a yellowish white thickening and deposit within the coats of the vessels, from a degeneration of the natural textures of the arterial walls, and weakness of the parts where it occurs. One or two ounces of serum, more or less, may be detected in the ventricles, and in the subarachnoid cellular tissue. Other changes may be observed in various parts of the brain, but the above are the most common. Sometimes tumors, cysts, old clots, purulent collections, thickening, injection, or ossifications of the membranes, etc., may be noticed. Where death occurs from reaction, the effects of inflammation will be seen.

"In subarachnoid hemorrhage the blood issues from a rupture in an artery or vein, mingles with the cerebro-spinal fluid, and has a constant tendency to spread into the ventricles of the brain, and into the spinal cavity, and false membranes are never met with. In intra-arachnoid hemorrhage, the blood is always given out by exhalation, never extends far from the spot where it is effused, and, there is constantly found, toward the fourth or rather the fifth day, a false membrane entirely enveloping the coagulum." (*M. Prus.*)

In most cases of apoplexy among aged persons, evidences of cardiac, renal, or hepatic disease will also be present; sometimes, of gout.

In the *treatment* of apoplexy during the attack, prompt and energetic measures will be required. The patient should be removed to a cool, airy place, and all bandages or cravats around the neck be removed. He should then be placed in a sitting posture, holding his head between the knees or in some other convenient manner, and a stream of cold water should be poured upon the head and neck by one person, while another holding some common salt in his hand, rubs it on the head and temples, until the patient is sufficiently restored to swallow an active purgative, as, for instance, the Compound Powder of Jalap. At the same time the limbs should be ligated, allowing the ligatures to remain on a sufficient length of time, but not too long.

If recovery does not readily ensue from these means, other derivative measures must be adopted, as, stimulating purgative injections, bastinadoing the feet, a drop or two of Croton Oil on the tongue, and stimulating applications to the inferior extremities. In many cases, advantage will be derived from dry cupping along the spinal column, and wet cupping on the nape of the neck and the temples.

The above treatment is especially designed for congestive cases, known by flushed or livid face, head hot, evident pulsations of the carotids, and hard, full pulse. But when the case is one of cerebral anemia, or feeble circulation, known by the paleness of the face, coldness of the surface, feeble and flickering pulse, a different course will be required; warm water should be poured upon the head and neck, stimulating applications should be used along the spinal column, and, if possible, the patient should be made to swallow some active stimulant.

After an attack of apoplexy, the patient should endeavor to prevent a subsequent one by pursuing the hygienic and therapeutic course, hereafter named, for those predisposed to the disease.

He should not rise too soon from bed, or expose himself to much mental or physical exercise, or to immoderate diet; by neglecting these precautions, a fresh extravasation of blood in the brain may be induced, productive of irreparable mischief.

But the chronist will seldom be called to treat a patient in the apoplectic seizure; he will be more apt to prescribe for the patient, either to prevent the attack when there is a predisposition to it, or to ward off a second or third attack, both of which will require similar measures, and which treatment, to be successful, must be steadily persisted in for three or four years. The treatment will consist of a proper and judicious combination of the measures advised for hyperemia of the brain, and ramollissement.

“The best physician is he who *watches* his patient most carefully. The wisest patient is he who submits—for *the rest of his life* it may be—to his physician’s injunctions; asking not ‘how little may I do?’ but, ‘how much can I do in my perilous case?’”

The therapeutical measures will consist principally in tonics and alteratives; the tonics, consisting of Sulphate of Quinia, Muriate of Berberina, Valerian, Carbonate of Ammonia, Arnica, etc. A very excellent preparation may be made as follows: take of Sulphate of Quinia two drachms, Elixir of Vitrol six fluidrachms, dissolve the Quinia, and add Tincture of Arnica three fluidounces; the dose is twenty or thirty drops, three or four times a day.—If the patient be anemic, small quantities of Iron should be taken daily, either in powder, tincture, or in his food; one to three grains of any preparation of Iron per day, will be fully sufficient, as the system will be unable to dispose of any more. Or, the Elixir of Iron and Cinchona may be administered with benefit.

As alteratives, the Iodide of Potassium, Iodide of Ammonium, Bromide of Potassium, Bromide of Ammonium, may be administered in conjunction with antiscrofulous, antisiphilitic, or diuretic syrups. Indeed, diuretics should never be omitted; a Solution of Acetate of Potassa will be found an admirable diuretic in this disease.

For the first ten days following the recovery from the attack, active purgation is unnecessary and dangerous; after this period, an occasional cathartic, especially when symptoms of headache, fulness, flushed cheeks, etc., are present, will be found serviceable. But, at all times, a most important measure is to keep up a regular, healthy condition of the alvine discharges; the bowels should be moved once a day, either by natural or artificial means. The surface of the body should be kept in a normal condition by frequent washings and friction; the use of the bath, that is, the full length

bathing tub, with either cold or warm water is apt to prove injurious, either directly or from reaction. Sometimes a persistent discharge from the nape of the neck, by means of the Compound Tar Plaster will be beneficial; but it should be at once omitted if it causes paleness, feebleness of pulse, or depression of mind or body. Paralysis attending apoplexy will be treated upon hereafter. (*See Hemiplegia.*)

All persons disposed to apoplexy should rigidly adhere to certain hygienic measures, to aid in strengthening their systems in removing the cause of the disease and a tendency to fatty degeneration, etc., and thereby preventing an attack. The slightest gastric irritation or stimulation is transmitted sympathetically to the brain, hence, though the diet should be nutritious, it should be light, easy of digestion, used in moderation, and great care should be taken to have the meals at regular hours, and to masticate the food thoroughly; suppers, especially, should be very light; animal diet should be used very sparingly during the hot summer months. All high seasoned food, stimulants, and intoxicating liquors should be positively avoided. All excesses or excitements should be avoided as much as possible, as, long-continued mental exertions, anger, or other mental excitements, late hours at night, and exercise immediately after a meal. Moderate exercise should be taken daily at regular hours, and in the open air as much as possible, but not sufficient to hurry the respiration, or greatly augment the temperature of the body. Venery should be indulged in as little as possible, and not at all, if there has already been an apoplectic attack. The neck should be kept free from all tight cravats, or other compression which might obstruct the return of blood from the head, or induce spasms in the muscles of the neck: the feet should be kept warm and dry; exposures to cold, and especially to cold feet are dangerous. Flatulency and gastric acidity should be promptly removed as soon as their presence is known. The hours of sleep should be regulated not to exceed ten hours in summer, and twelve hours in winter, and the bed should be a hard mattress, having the head somewhat elevated; and for at least two hours previous to retiring to bed no food must be allowed to enter the stomach. Good, pure air in the rooms at home, as well as when abroad, is an important item; and the bedroom should always be well ventilated, or be so arranged as to permit a free circulation of air during the night. Direct exposure to the sun's rays in hot weather should invariably be shunned; neither should the head be exposed to the continued action of any kind of heat. Sudden turning of the head, or straining the muscles of the neck to look upward, sideways, or behind should

also be carefully avoided, as it is liable to induce spasm of the muscles of the neck, (*trachelismus*)—also straining at stool, lifting heavy weights, etc. During warm weather, and especially when there is giddiness, headache, flushed face, and other symptoms of a hyperemic disposition, cold water poured on the back of the head and along the spinal column, will be found a very pleasant, safe, and salutary measure; in winter, the water may be slightly warmed. If there be giddiness, faintness, headache, sickness at stomach, and paleness of the countenance, instead of being cold or blood-warm, the water employed should be as hot as can be borne by the patient, with some diffusive stimulant administered internally. Without the most rigid attention to the therapeutic means above recommended, and to the rules of hygiene generally, it will be a very difficult matter to prevent an attack of apoplexy in those predisposed to it; while, on the other hand, care and prudence in observing them, with a persistent use of them, will remove the tendency, and be productive of the most essential benefit.

The urine should be tested for albumen in all cases, and if any renal disease be detected, or if disease of the heart or liver, be present, affections which frequently cause or aggravate the conditions of the brain leading to apoplexy, they should be treated accordingly, in addition to the preceding measures named. (*See Treatment of Lesions of the Orifices and Valves of the Heart.*)

PARALYSIS.

Paralysis, or Palsy, is a diminution of mobility, or sensibility, or a partial loss of control or power over one or both of them; it may be confined to one part of the body, or be extended to several parts. It is not an actual disease itself, but is merely a symptom indicative of some more or less serious disease; which disease we should always endeavor to determine, as far as possible, before adopting treatment to remove or ameliorate the palsy. When the motion or sensation is wholly lost, the paralysis is said to be *complete*; when not entirely lost, it is *incomplete*. When only one function is affected, the paralysis is *imperfect*; when both the functions of motion and sensation are lost, it is *perfect*. And these conditions may exist together in several ways.

When paralysis is confined to a single limb, or to certain muscles of one part of the body, it is called *local* or *partial paralysis*; when one complete half of the body, from the head to the foot, is affected, it is termed *hemiplegia*; when the lower half of the body, from the hips downward, is affected in a transverse direction, it is called *para-*

plegia; and when there is a constant tremor attending a state of incomplete paralysis, it is termed *shaking palsy*, though this condition will frequently be found a symptom of chorea instead of paralysis.

As a general rule, the *prognosis* of paralysis is unfavorable; especially those forms due to disease of the brain,—though if we can excite reflex movements in the affected limbs, as, causing motion in them by applying a hot iron, tickling a foot, etc., there is some grounds for hope. A sudden attack of paralysis without coma, is not due to cerebral hemorrhage, and, therefore, is not apoplectic; it may be caused by softening of the brain, or by hemorrhage into the spinal column, in which case there is severe pain in the spinal column at some point, and the palsy is usually double-sided; and, if the effusion is in the meninges, tetanic tonic spasms occur.

Dr. R. B. Todd says, “Whatever interferes materially with the conducting power of nerve-fiber, or the generating power of nerve-vesicles (gray matter), will constitute a paralyzing lesion. Thus, in the first place, poisoning of the nerve-matter will operate in this way. Soak a portion of the nerve of a living animal in chloroform, or ether, or opium, and it will fail to propagate the nervous force as long as the influence of the poison lasts. In a similar way, the poison of lead in the living system may paralyze by weakening the conducting or generating power of the nervous matter. Poisons formed in the living system may operate in the same way; such as retained urinary or biliary principles, or the poison of rheumatism and gout. Secondly, any morbid process which greatly impairs the natural structure of nerve-matter will paralyze. Thus, inflammation will do this; so also will atrophy, or wasting from want of sufficient supplies of nutrient matter, as when the flow of blood is lessened or cut off. The opposite conditions of hardening and of softening of the nervous matter become paralyzing lesions for the same reason that they greatly impair or destroy the nerve-structure. Thirdly, a solution of continuity of nerve-fiber will paralyze. Cut a nerve across, and you have immediate palsy of the parts which the nerve supplies below the section. This solution of continuity from a melting down of the fibers, is, I have no doubt, the frequent cause of sudden paralysis in cases of softening, or in cases of sanguineous effusions. Fourthly, pressure on a nerve or nervous center will paralyze. Of this we have many proofs as regards nerves; a nerve, for instance, included in a ligature, or compressed by a tumor, is paralyzed thereby. A fracture of the skull, with depressed bone, will paralyze if the brain be sufficiently compressed; an apoplectic clot on the exterior of the brain paralyzes by compression; so also

does a tumor in its substance. It is probably by compression that congestion paralyzes; but you will, I think, find that this can not often be regarded as a paralyzing lesion.

"I would say that the center of volition is of very great extent; it reaches from the corpora striata, in the brain, down the entire length of the anterior horns of the gray matter of the spinal cord, and includes the locus niger in the crus cerebri, and much of the vesicular matter of the mesocephale, and of the medulla oblongata. Disease of any part of this center is capable of producing paralysis; but as the intracranial portion of it exercises the greatest and most extended influence in the production of voluntary movements, so disease of this portion gives rise to the most extended and complete paralysis. Another fact which I would impress upon you, is, one which anatomy in a great degree demonstrates, and which pathological research confirms, that the center of volition for either side of the body, is not altogether on the same side of the body. Of the center for the left side of the body for instance, the intra-cranial portion is on the right side, and these two portions are brought into connection with each other through certain oblique fibers from the anterior pyramidal columns of the medulla oblongata, which cross from right to left, decussating with similar fibers proceeding from left to right, which belong to the center of volition for the right side of the body."

Dr. Brown-Sequard advances the following views based upon the results of observations and experiments instituted by himself:

"1. The gray matter of the spinal cord is the principal channel by which sensitive impressions are conveyed to the brain.

"2. The anterior columns have a share in the transmission of sensitive impressions.

"3. Injury of one lateral half of the cerebro-spinal axis produces certain well-marked features, according to the following table:

"a. Injury of the brain produces—

<i>On same side.</i>	<i>On opposite side.</i>
Anæsthesia.	Normal sensation.
Paralysis.	Normal motor power.
Increased temperature.	Normal heat.

"b. Injury at any point from the tubercula quadrigemina, to the medulla oblongata above the decussation in the pyramids, produces—

<i>On same side.</i>	<i>On opposite side.</i>
Anæsthesia.	Hyperæsthesia.
Paralysis.	No paralysis.
Diminished temperature.	Increased temperature.

"*c.* Injury of the medulla oblongata at the crossing in the pyramids produces paralysis of motion on both sides; otherwise the symptoms are the same as in *b*, when the pons Varolii is injured.

"*d.* Injury of the spinal cord on one side produces—

<i>On same side.</i>	<i>On opposite side.</i>
Anæsthesia.	Hyperæsthesia.
No paralysis.	Paralysis.
Diminished temperature.	Increased temperature.

"Anæsthesia and diminished temperature almost always accompany each other; but an exception is observed in Class *a*—injury of the brain proper. This may possibly be explained by the fact that the nerves, with which the blood-vessels are supplied decussate, in the cerebro-spinal axis at a higher point than the ordinary sensitive nerves—apparently above the corpora quadrigemina. Hence, if the brain proper be divided on one side, dilatation of the blood-vessels on the opposite side will be produced. The occurrence of increased temperature on the paralyzed side in injuries of the brain has frequently escaped notice; though frequent, it can scarcely be said to be a constant phenomenon."

There are several varieties of paralysis, the most frequent and serious being 1st, those which arise from some interruption between the volitional centers and the muscles, from inflammation and its consequences, from pressure by tumors, depressed fractures, effusions, etc., and 2d, those in which no such interruption can be found, except as a result and not a determining cause. Among the latter may be named the following:

1. PARALYSIS FROM POISONS. The articles more commonly known as giving rise to paralysis, are, lead, mercury, arsenic, ergot, aconite, and stramonium. *Lead palsy* is commonly preceded by one or more attacks of colic, though it may occur without. Indeed, one of the worst cases I ever saw of lead colic, in which one arm and both legs below the knees were paralyzed, had never been preceded nor attended by any affection of the digestive organs, except an occasional obstinate constipation. Usually, however, the paralysis appears after an attack or two of colic, and constipation, colicky pains, and other derangements of the digestive organs are apt to manifest themselves at various times, both before and after paralysis has occurred. Both the extensor and flexor muscles are affected. More commonly the extensor muscles of the upper extremities are the most affected, so that the fingers are bent when the arm is raised, (*wrist drop*), and sometimes they can hardly be raised at all, the palsy being generally incomplete. When one arm is severely affected, the patient ordinarily raises it by the assistance of the other.

At times, one or more fingers are permanently flexed; when this is not the case, although the patient may not be able to move the arm, or extend the fingers, yet he may have a tolerable good grasp of whatever is put into his hand.

Pains in the limbs are usual attendants, and not unfrequently deafness. Gradual emaciation of the affected muscles almost invariably attends this affection. Sensibility is not ordinarily diminished; indeed, pains shooting through the affected limbs are common.

In lead palsy, as a *diagnosis*, in addition to the symptoms above named, there will be a morbid dead-like appearance of the gums, while the whole or some parts of their edges will exhibit a narrow leaden blue line, about the twentieth of an inch in width, and which symptom is peculiar to all persons whose systems have absorbed lead.—If galvanism be applied to the paralyzed parts—“if the excitability of the muscles, or, rather the polarity of the motor nerves, be *increased* in the paralyzed limb, the case is one of *cerebral paralysis*, connected with an irritative lesion within the cranium. If the excitability of the muscles be nearly or totally *lost*, we have, in all probability, either *lead palsy* or *traumatic paralysis*, (spinal); but it must be kept in mind that certain hysterical and rheumatic palsies of long standing present the same peculiarity; and that it may also be found in cases of disease of the brain and the cord. *If paralyzed muscles respond readily to the galvanic current*, there is no lead in the system, nor is the connection between the motor nerves of the paralyzed muscles and the cord interrupted; but if such cases are of *long standing*, they are due to *brain disease*; and if they are of *recent standing*, they are generally instances of *hysterical, rheumatic, or spontaneous paralysis*.” (Althaus.)

Again, lead paralysis is common among those who work in lead mines, also among white lead manufacturers, house painters, card manufacturers, and workers in the metal generally.

The *prognosis* of lead palsy when recent is more favorable than when of long standing; it is also less favorable when the inferior extremities are affected.

The *pathological appearances* vary; the paralyzed muscles are usually pale, bloodless, and flaccid, and, in long-standing cases, fibrous. The nerves have also been found atrophied and more dense than natural. As an effect, softening of the pons Varolii, of the substance of the cord, injection of the pia mater, medulla oblongata, and medulla spinallis, dryness of the membranes of the cord, etc., have been observed. Lead has also been detected in the urine, blood, bile, liver, in the palsied parts, in the cerebellum, etc.

Paralysis from mercury may come on gradually or suddenly, with

slight convulsive agitations of the muscles of the arms, followed by tremors, and which extend gradually to the inferior extremities, and over the whole body. In connection with which there is an incapability of muscular exertion, as well as some of the symptoms peculiar to mercurial poisoning. This disease attacks those who are exposed to the fumes of mercury, or who are subjected to its influence either by internal administration or by external inunction. It resembles shaking palsy, and is termed by the French, *tremblement métallique*. The disease is considered curable, though sometimes it remains incurable; it is rarely fatal.

Paralysis from arsenic is occasionally met with, which may be limited or partial, which sometimes resembles lead palsy, with contractions of the joints, and in which both the functions of sensation and motion are affected. It is of difficult cure.—*Paralysis from narcotics* is also of rare occurrence, limited in its action, and usually curable.—*Paralysis from ergot*, a rare affection, more commonly involves the function of sensation.

In the *treatment* of this variety of paralysis, the patient should at once avoid the causes producing it; leaving off his trade, if he be a worker in lead, mercury, etc., and ceasing the use of the other agents referred to. Internally, the following may be given: Take of Iodide of Potassium eight scruples, Water four fluidounces; mix. The dose is a teaspoonful four times a day, and should be continued not only until lead can not be detected in the urine and saliva, but for some time afterward. If much pain be present, one-eighth of a grain of Sulphate of Morphia may be added to each dose. Any tendency to delirium, convulsions, epilepsy, or coma, may frequently be diminished or overcome by the internal administration of Extract of Belladonna.

To combat the paralysis, Strychnia should be used internally, and electro-magnetism be applied to the affected muscles, not the continuous current, but only induction currents. Strychnia will also be found useful when sprinkled upon a blistered surface made over the affected muscles; of course, this application should be made with great care, and over a limited portion only at a time.

Purgatives should be administered every day or two; and the body should be washed every day with soap and water. Sulphur, or Sulphur and Iodine baths may also be taken,* and in mercurial paralysis, Sulphur may be exhibited internally.

* These baths are made by heating the sulphur, or sulphur and iodine, and exposing the naked body of the patient to the fumes arising therefrom, while seated in an air-tight bath-box, the head being free and protected from the vapors.

In the paralysis from narcotic poisons, the internal use of Iodide of Potassium may be dispensed with ; though internal and external stimulants will be found advantageous.

2. WASTING PALSY, or *Progressive Atrophic Muscular Palsy*, also called “Cruveilhier’s Atrophy,” “Creeping Palsy,” “Peripheric Palsy,” etc., is a peculiar affection, the most striking characteristic of which is the wasting away of the muscles of the life of relation or of animal life—those that are under the control of the will—and to which it is strictly confined. This atrophy occurs independently of lead poisoning, or of any disease of the brain or cord. Sir Charles Bell remarks that the disease is a morbid affection of muscles acting under a law of election, that limits the progressive wasting to those muscles only that are naturally combined in action ;—but by no means invariably so.

The *cause* of this affection is not well understood ; it appears to be hereditary, in which case it is more common to males, and is of a more fatal form. The suspected causes are, undue muscular exertion, exposure to cold, protracted fatigue or straining of muscles, and bruises. It may occur in males or females who are apparently perfectly healthy, who have received no injury, nor been subject to any great exposure, coming on, as it were, without any assignable cause.

The *symptoms* of this disease are not readily recognized at first, as it comes on slowly and insidiously, creeping on unawares ; and the patient only becomes aware of its presence from the sensible loss of muscular power—perhaps in many muscles. After the disease has made a certain progress, the affected muscles become atrophied, or soft and degenerated. As these muscles disappear, very notable changes of configuration occur, “the symmetrical contour gives place to a lean and withered aspect ; the bony levers stand out in unaccustomed distinctness, and impart to the limb the appearance of a skeleton clothed in skin ; but the skin itself, and the subcutaneous cellular tissue, have undergone no change, and can not be distinguished from the integument of healthy parts. But loss of substance is not the only anatomical change observed. The natural equilibrium of the muscular forces is overset by the unequal wasting of the muscles ; those less atrophied overcoming the resistance of those more deeply diseased. Hence arise very considerable, and sometimes peculiar distortions of the head, trunk, and extremities.”

“But, perhaps, the most remarkable of all the anatomical changes are seen in the face, when the muscles of expression are destroyed. The intelligent countenance is veiled, as it were, by an impenetrable mask ; no emotion changes its unvarying aspect—

always solemn, stolid, and unmoved. The eyes, however, are spared, (their muscles as well as those of mastication being exempt from the disease), and by their movements alone, in the last periods, the immortal part holds some imperfect communion with the world around."

When the muscles of the interior are attacked, the tongue will be affected, known at an early period by a slight faltering in speech; mastication and deglutition become difficult; the tongue can not move about in the mouth, nor be protruded properly, and it has a soft feeling, and is often the seat of tremblings. The voice changes gradually to a single note, when the laryngeal muscles are affected; and when the diaphragm and intercostals become involved, violent, suffocative fits of coughing occur, and the play of the chest is reduced to a slight movement in the lower ribs.

With the loss of power and atrophy of the muscles there will be slight convulsive twittings or quiverings in them, which impart no motion to the entire muscle, but undulate over its surface, beneath the skin, in quick momentary tremors, becoming more frequent and vivid when the skin is tickled, when active movements are attempted, when the affected muscle is raised, or upon the application of cold. These quiverings are not always present, but when they are, they indicate the advance of the disease, ceasing only when the disease is arrested, or the muscles are entirely destroyed. They are not constant, but come on at irregular periods, spontaneously, or when excited by cold air, pressure, or tickling, and cause no pain. Cramps and twitches may also be present, but they are not essential symptoms. The affected muscle gradually loses its contractility under electric action. As a general rule sensibility is not impaired, the special muscular sense surviving to the last. Pain is frequently present, it may be severe or dull, but gradually ceases as the atrophy progresses. The twittings, cramps, contractions, pains, etc., are reflected phenomena. Sometimes singular positions are given to the body, the consequence of antagonism between the healthy and affected muscles. In every respect, except the muscular atrophy, the whole of the organic functions are performed with perfect regularity.

The more common complications of wasting palsy are neuralgic affections, tuberculosis, albuminaria, and mollities ossium.

The muscles of the extremities are more liable to be attacked by the disease than those of the trunk; and those of the superior more so than those of the inferior extremities; the right arm more frequently than the left, and the hands oftener than the shoulders. The fore-arm and hand, the upper arm and shoulders, are favorite

combinations. "When the hand and fore-arm are destroyed, the disease does not then pass up the arm, but starts away to the shoulder or to the opposite hand. In the same way when the shoulder is first attacked, the disease does not descend along the upper and fore-arm to the hand, but, passing over the elbow, it begins afresh in the ball of the thumb, and from that focus spreads up the limb, so that the parts latest reached are those about the elbow, especially the masses that take their rise from the humeral condyles."

General atrophy of the muscles may occur at any period from childhood to old age; the partial form is seldom observed except in persons between twenty and fifty years of age.

The *diagnosis* of wasting palsy is not very difficult. It may be discriminated from *paralysis caused by injury or pressure* on a motor nerve, by this being strictly limited to the parts supplied by the affected nerve; and, if the nerve be a mixed one, by an accompanying loss of sensation. From *cerebral hemiplegia*, by its more gradual appearance, by the rapid but irregular occurrence of the atrophy, and by the absence of those mental disturbances, and other symptoms, indicative of brain-lesion. From *general spinal palsy*, in which the muscles of the inferior extremities are affected before those of the superior. From *rheumatic paralysis*, in which certain groups of muscles are affected, instead of a muscle here and there as in wasting palsy; besides, electricity causes pain in the atrophied muscles of rheumatic paralysis, as well as contractions, both of which are usually absent in the disease under consideration. From *lead palsy*, by its more sudden invasion, its involving the exterior muscles more especially, the diminution of electric contractility, and the very slow diminution in size, if at all, of the affected muscle. Wasting palsy slowly extends itself, the affected muscles only gradually lose their electric contractility, and the atrophy of the muscle continues until it has wholly disappeared.

Wasting palsy is a formidable malady, and its *prognosis* is by no means favorable, even in the more recent cases; though the disease may terminate in recovery, with very slight, or perhaps no deformity; or in permanent *arrest* with more decided deformity, and death. "When the atrophy has extensively affected the muscles of the trunk, or has remained stationary for a lengthened period, the chance of recovery diminishes in an accelerated ratio." When the muscles of the trunk become affected, it is apt to quickly terminate fatally; when the palsy is present in a partial form, it is not necessarily fatal, unless the atrophy, by extension, passes into the more serious type, or general atrophy.

The *pathological appearances* are a greater or less wasting away of the muscles, which exhibit a pale-red, ochrey-red, pale-yellow, or buff color, with, occasionally, yellow streaks of fat between the redder bundles. Sometimes atrophy without fatty degeneration will be observed, and, again, masses of pure fat are present, with scarcely a trace of muscular fiber. The degeneration of the muscular fibrille is sometimes fatty, and at other times, entirely granular. The nerves may be healthy; but, frequently, the motor nerves may be atrophied with fatty degeneration, and perhaps softening, or some other change in the spinal cord,—these, however, are not invariably present, being secondary or reversed phenomena.

In the *treatment* of this disease, the principal object is to arrest or cure the atrophy of the muscles and combat the fatty or granular degeneration. For this reason all exciting causes should be avoided; patients must at once renounce their business pursuits, in order to relieve the muscles from strain or fatigue; and all exposures to cold and moisture should be especially guarded against. The muscles must be subjected to perfect repose and well-regulated stimulation, judiciously combined. As long as the muscles manifest the least signs of electric response, even if only by the smallest fibril wave or contraction, galvanism should be used daily, or every other day. Each muscle should be caused to contract as strongly as possible. Great power with very rapid vibrations should be employed, diminishing the intensity of the electro-magnetic current, as the sensibility of the muscles returns; and the current should be made to pass through the affected muscles, and not along the nerves leading to them, nor into the spinal cord. Ten or fifteen minutes at a time is enough, lest the muscles become exhausted. And this course should be perseveringly pursued for many months. The parts should be kept warm; no benefit can be expected to take place in any part kept cold. Moderate shampooing,—circular shampooing in particular—of the affected muscles, repeated daily, will also be of considerable service, care being taken not to fatigue or overwork them. And, in connection with these, stimulating liniments may be applied to the parts by gentle frictions; a very excellent liniment for this purpose is the following: Take of Tincture of Camphor, Tincture of Capsicum, each, one fluid ounce, Tincture of Nux Vomica two fluidrachms, Glycerin one fluidounce; mix and add to it a solution of Bromide of Ammonium twenty grains, in Distilled Water half a fluidounce. Shake thoroughly together before using. Warm saline or sulphureted baths may also be occasionally employed. Internally,

Bromide of Ammonium, or Iodide of Ammonium may be used, together with such other measures as are calculated to remove any existing derangements of the digestive and nutritive functions, as well as any local or general disease. The following solution will be found very advantageous: Take of Bromide of Ammonium one ounce, Water one pint, dissolve and add Citrate of Iron and Strychnia six hundred and forty grains. The dose is a teaspoonful three or four times a day. Arnica may also be beneficially employed in some cases, both as an internal and external medication.

To remove the pains, when severe, warm baths, and sedative liniments along the painful track will be of service, as the following preparation: Take of Chloroform, Tincture of Aconite, Laudanum, Tincture of Camphor, equal parts; mix.

3. REFLEX PARALYSIS. (White or Non-Inflammatory Softening of the Cord. (*Brown-Sequard*.) This includes paralysis following certain diseases, infantile paralysis, facial and certain other local paralyzes, and hysterical paralysis. Thus, the endemic colic of hot countries, and zymotic diseases, as, dysentery, continued and eruptive fevers, cholera, diphtheria, etc., as well as diseases of the uterus, the urethra, bladder, prostate, kidneys, bowels, lungs, liver, etc., together with worms, dentition, neuralgia, and other painful affections, may all be followed by paralysis;—generally paraplegia.

Dr. T. Spencer Wells, says:—"When a patient comes to you with a tottering gait, complaining of weakness of the knees, a tendency to stumble in going up and down stairs, or on any uneven ground, and a certain loss of that muscular sense which enables us to walk without watching the feet to know where to place them at every step, your first impression will be very naturally that you have to deal with a case of spinal disease. Your first impression may be correct. As you proceed with your examination of the case you may obtain evidence of some injury to the spine, some distortion of the bones, some displacement from caries of the bodies of the vertebræ or ulceration of the intervertebral cartilages, some point at which pressure, or a sharp tap, or a hot sponge, causes pain—some history of inflammation of the cord—some indication of the pressure of a tumor, or of an aneurism of the cord—or possibly some proof that the disease is within the cranium. But you may find nothing of the kind. You have to exclude all these, and you are driven to assume a diseased condition of the lower portion of the cord, perhaps a simple atrophy, of the existence of which you have no other proofs than the paraplegic symptoms I have just enumerated. Let me convince you that you can have all these symptoms,

that they may go on to complete paraplegia, and the patient may die, and that then you may find the cord perfectly healthy, so far as our examination can teach us, while the kidneys and bladder" (uterus, urethra, prostate, seminal vessels, etc.), "are the seat of manifest disease."

Dr. Brown-Sequard, who has devoted much time and labor to the investigations of this class of diseases, and to whose writings I am considerably indebted in the subsequent remarks on the subject of paralysis, attributes reflex paralysis to what he terms an outside irritation starting from a sensitive nerve or nerves of the diseased organ or parts, which, being conveyed to the spinal nervous center, produces a paraplegia by a contraction rather of the blood-vessels of the spinal cord, than of those of the motor nerves and muscles; and, he adds, it is not rare, in reflex paraplegia, that a notable diminution of temperature of the paralyzed limbs shows that the blood-vessels of these parts are also contracted. This condition of the blood-vessels of the cord is followed by an insufficiency of nutrition, and hence, from these several causes, by the reflex paralysis; and, if this condition be allowed to continue, it may ultimately give rise to myelitis or some other affection of the cord.

There is, likewise, a second form of reflex paraplegia depending upon an alteration of nutrition in the muscles of the lower limbs, the result of pressure upon the blood-vessels supplying the limbs, or upon the nerves of the lumbo-sacral plexus. This form of paralysis may be determined from the preceding, by the existence of violent pains in the pelvis, and in many parts of the lower limbs, by the production of cramps, by a rapid atrophy of the muscles, etc.

Paraplegia connected with gout, rheumatism, or following serious fevers, cholera, diphtheria, etc., usually depends upon a serous effusion in the spinal canal, or a venous congestion, and, sometimes, it belongs to the group of reflex paralysis.

Whether the above causes named by Brown-Sequard are truly correct, has yet to be determined by still further investigations,—the reasons he gives for them are very strong and plausible, and have not yet been refuted.*

In the *diagnosis* of reflex paralysis, it is absolutely necessary to determine between it and those cases of paralysis which are due to

* Prof. Brown-Sequard has published the following works which contain much new and important information, principally the result of his own researches, and which volumes should find a place in the library of every medical man: "Researches on Epilepsy," "Lectures on the Diagnosis and Treatment of the Principal Forms of Paralysis in the Lower Extremities," "Course of Lectures on the Physiology and Pathology of the Central Nervous System."

disease of the spinal cord; as the medicines which are useful and efficacious in the one kind, are highly injurious in the other. Reflex paralysis may be detected by the absence of the special symptoms of an *organic disease of the spine* or its contents, such as, severe pain in some part of the spinal column, soreness or pain in some part of the spinal column when percussed, the inutility of all remedies applied to the spine, or to the general nervous system only, the presence of one or more of the following symptoms, viz., convulsions, cramp, twitchings, erections of the penis, formication, itching, diminution of temperature, wasting of muscles, œdema, bed-sores, and alkaline urine; and also by the existence of an incomplete paralysis of the lower limbs that has appeared somewhat *slowly after* a disease of the urinary or genital organs, or of some other abdominal viscus; *after* an inflammation of the lungs or pleura, or *after* some other kind of irritation of a nerve in its trunk or cutaneous ramifications. In reflex paraplegia there is no organic disease of the spinal cord; the paralysis will rapidly disappear when the source of reflex irritation is cut off; and the vascular supply of cord, of motor nerves, and of muscles is under the influence of reflex action. (*See Diagnosis of Paraplegia.*)

The *prognosis* of reflex paralysis depends in a great measure on the severity of the external disease which has induced it. If it does not arise from organic disease or other cause which is in itself generally fatal, it will often admit of cure, and that, perhaps, very rapidly. As a general rule, so long as the external morbid condition, which has produced it, lasts, the paralysis persists, and it ceases very quickly, and sometimes without any special treatment, after this morbid condition has been cured. In some cases, however, as when caused by cold, or disease of the bowels, the paralysis persists long after its external cause has been removed. When the paralysis depends upon a defect in the nutrition of the cord, it is almost always curable; but when it is due to an alteration of nutrition in the muscles of the lower limbs, recovery rarely takes place, even though the provoking cause of the paralysis be removed,—because, the muscles have become rapidly atrophied and altered.

In the *treatment* of reflex paralysis the first thing to be done is to ascertain the disease or irritation that has produced it, in order that means may be employed to cure or alleviate it. This necessarily involves the consideration of the treatment of nephritis, cystitis, morbid states of the uterus, enteritis, etc., which it is not required to enter upon here. While attempting the cure, a very important indication is, to allay irritation and pain, by diminishing the sensibility or interrupting the nervous influence which passes from the

diseased organ or nerve to the spinal cord, to paralyze the sensitive nerves. The agents that may be employed for this purpose are Belladonna, Chloroform, or Morphia, locally applied, or Morphia internally. Dr. Brown-Sequard states that to diminish pain, or to prevent reflex action, no narcotic is more powerful than Belladonna locally employed; it should be applied as much as possible to the organs from which starts the external cause of the paralysis.*

* It may be serviceable to the practitioner, to name, at this place, the therapeutical action of certain agents, which the results of experiments have induced some physiologists to advance, especially Dr. Brown-Sequard.

Strychnia and *Brucea* have similar effects. *Strychnia* increases the quantity of the blood in the spinal cord, and hence is not useful when there is a congestion of the cord; it localizes its action entirely upon the sensitive nerves; it is injurious in epilepsy and paralysis arising from lesions of the encephalon, or congestion of the spinal cord; is useless in chorea and paralysis agitans; but, in small doses, is useful in slight paralysis due to white softening of the spinal cord, and in all cases of functional derangement from want of nervous power. It should be employed in paraplegia without irritation or without increase of the vital properties of the spinal cord, as in cases of reflex paraplegia, and white or non-inflammatory softening of the cord. It should be avoided in paralysis with symptoms of congestion, spinal meningitis or myelitis. (B.-S.) It is more useful in paraplegia than in hemiplegia.

Ergot (spurred rye), diminishes the blood in the spinal cord, by causing a contraction of its blood-vessels; dilates the pupil; acts more especially on the muscular fibers of the womb, and of the bladder and urethra, and appears to exert a more powerful influence on the inferior portion of the spinal cord. It should be used in the same forms of paralysis, and disease of the spinal cord, as Belladonna. (B.-S.)

Belladonna diminishes the blood in the spinal cord, and hence diminishes the vital properties of it and its nerves; dilates the pupil; causes the secretion of milk to cease; is useful in strangulated hernia, nocturnal incontinence of urine, etc. Belladonna, and its congeners, *Hyoscyamus*, *Stramonium*, *Indian Hemp*, etc., have a depressant influence on the pneumogastric nerve, excites the sympathetic, and depresses the cerebro-spinal system; they touch the secretions, and are slightly aperient; young children require proportionally larger doses to affect them. Belladonna imparts tone to most involuntary muscles, causes wakefulness, restlessness, is a powerful excitant of the blood-vessels, and, in large doses, causes delirium; it is useful in external neuralgia, in congestive headache, and coma with contracted pupil, in paraplegia with symptoms of irritation of the motor, sensitive, and vaso-motor, or nutritive nerve-fibers of the spinal cord, or of the roots of its nerves, as in spinal congestion, meningitis, myelitis, etc. It is a dangerous agent in paraplegia without symptoms of irritation, as in cases of white softening, or of the reflex paraplegia, in which cases it is likewise improper to administer its congeners and Ergot. In paraplegia, with symptoms of irritation of the spinal cord, where sleeplessness is present, *Hyoscyamus* should be used instead of Belladonna, or Opium. (B.-S.)

Sulphur is useful in cases of reflex paraplegia, or white softening of the cord without irritation. (B.-S.)

Iodide of Potassium (and probably also the *Bromide*, as well as the *Iodide* and

Thus, in disease of the urethra or of the prostate, a mixture of one grain of Extract of Belladonna in twenty drops of Laudanum should be injected into the urethra, and after half an hour or an hour's rest there, be washed away by some emollient injection. This should be repeated every two or three days; using in the interven-

Bromide of Ammonium), may be employed without danger in the various forms of paraplegia; it is a powerful agent in promoting absorption of fluids effused in the cranio-vertebral cavity, either out of or in the substance of the nervous centers, and is not so depressing as other agents; it is especially useful in white softening of the spinal cord due to fatty degeneration of the blood-vessels of that organ; it has a rapid curative influence in syphilitic paraplegia. (B.-S.)

Sulphate of Quinia in large doses of 8 or 9 grains acts more on the ganglionic nerves, and subdues nervous action. In small doses of 1 or 2 grains, it elevates the principal vital actions, stimulating the circulation, respiration and nutrition; increases the resisting power of the nervous system to miasma; lessens the influence of opium, and exerts a tonic influence upon the vaso-motor or sympathetic nerves, without causing cerebral congestion. In paraplegia, it, as well as *Ammonia* and *Iron*, is useful in cases of insufficiency of the amount of blood in the spinal cord, as well as in deficiency of its nutrition; but they may also be used in chronic myelitis, or meningitis, or in spinal congestion, where the symptoms of irritation are not violent, and the pulse is weak and slow. (B.-S.)

Arsenic and the *Oxide of Carbon* acts upon the blood-globules. —

Cod Liver Oil in conjunction with Belladonna and Ergot is very useful in chronic myelitis and meningitis. (B.-S.)

Bleeding or *Cupping* is not required in chronic inflammations of the spinal cord; *Dry Cupping* is useful in cases where there is congestion or inflammation, but would be unsafe in white softening or reflex paralysis. (B.-S.)

Compound Tar Plaster, *Actual Caustery*, *Issue*, etc., are valuable in myelitis or meningitis, especially when the inflammation of the spinal cord or its membranes is limited to a small extent; they are useless in white softening and reflex paralysis. (B.-S.)

Cold Douche, *Cold Shower Bath*, *Sponging with Cold Water*, are useful in white softening and reflex paraplegia. (B.-S.)

Hot Douche, 100° F., applied on the spinal column over the painful part is very useful in congestion or inflammation of the cord, but is hurtful in white softening and reflex paraplegia. (B.-S.)

Ether is an expectorant; it dissolves as well as stimulates the bronchial epithelium.

Veratrum Viride, as well as *Veratria*, is an arterial sedative, or rather a nervous sedative, acting through the nerves, and especially the par vagum; it reduces the action of the heart, and exerts an influence primarily upon the cerebro-spinal system of voluntary nerves.

Bitartrate of Potassa is a diuretic; it dissolves the epithelial cells of the kidneys and liver.

Aconite moderates the force and frequency of the heart's action, and has a tendency to lessen pain and nervous irritation.

Hydrocyanic Acid is a prompt and efficient sedative; in appropriate doses it lowers the sensibility of the nervous system, moderates the force and frequency

ing days an injection of thirty drops of Laudanum only. In bladder disease, the aforesaid solution of Belladonna in Laudanum is to be injected every other day, immediately after evacuating the urine; using on the alternate days the Laudanum injection aloné. Daily injections of cool or tepid water will also be found to relieve irritability of this organ in many instances.

When there is an enlarged prostate, a suppository covered with a Belladonna and Opium ointment, ought to be placed occasionally, or as often as required, in the rectum. If the irritation radiate from the vagina or uterus, then a pill of half a grain of Extract of Belladonna with one grain of Opium, surrounded by a thin piece of cotton-wool, may be introduced into the vagina as far up as possible; from which it may be removed, by means of a thread attached to the cotton, as soon as the pain has ceased, or much diminished. If dysentery, colitis, or other morbid irritations of the large intestine be the seat of the local trouble, injections of Opium alone should be used. If dentition, enteritis, neuralgia, gastric, hepatic, renal, or pleuritic affection be the seat of local irritation, Opium or Morphia should chiefly be employed to relieve the pain and irritation. Belladonna should never be used in reflex paraplegia, without employing at the same time Strychnia and Opium, or at least Strychnia; and when Belladonna is employed it should not be constant. The great object of this narcotic treatment is to effect a dilatation of the blood-vessels of the spinal cord, that the blood circulating in them may be increased in amount. Strychnia alone may be used in doses of one-twentieth of a grain daily; if united with Opium, in doses of one-thirtieth to one-fortieth of a grain; if with Belladonna, one-twelfth

of the heart's action, and induces a sensation of quiet and calm throughout the whole system.

Digitalis depresses the circulation by hyperstimulation of the vaso-motor nerves; it reduces the heart's action.

Nitrate of Ammonia, in 15 grain does repeated three times a day, is a means of introducing an increased quantity of oxygen in the system, and may be found useful in fatty degenerations, diabetes, obesity, etc.

Opium in large doses produces congestion of the spinal cord, and unconsciousness; it is useful in reflex paraplegia; in delirium tremens with dilated pupils, but not when there is compression of the brain; all internal pains; checks all the secretions save that of the skin; lessens the tone of most involuntary muscles; constipates; and should not be employed in cases dependent on congestion, inflammation, or organic lesion of the nervous centers. It acts as a sedative, produces sleep, and lessens the intoxicating effect of quinia. It is considered a depressant to the cerebro-spinal and sympathetic systems.

Coffee and Tea increase nervous energy, and protract the metamorphosis of tissue; they, as well as *Cocoa*, lessen the elimination of urea.

Chloride of Sodium favors the formation and elimination of urea.

to one-fifteenth of a grain, this large dose being necessary to compete with the antagonistic action of Belladonna.

In addition to these measures, powerfully stimulating liniments, or excitants should be applied to the skin of the legs; galvanism to the paralyzed muscles, as well as shampooing; cold douche, thrown with great force for a minute or two, all along the dorsal and lumbar regions of the spinal column—the water should be at 40° or 50°, and be thrown in a small jet—and, immediately after its application, the spinal column must be rubbed with a hard, warm flannel. If patients can not bear a cold douche, use a warm one. In some cases alternate douches of ice-cold water followed by those of warm water, 100° F., will be of service.

To increase the blood in the spinal cord, three or four times a day, the patient should lie upon his back, having his head, arms, and legs on high pillows, so as to produce by gravitation a congestion in the spinal cord. All remedies used should be those which increase the amount of blood in the spinal cord, augmenting the vital properties of this nervous center, and also those remedies which render the blood richer in nutritive principles. The patients must exercise considerably in the open air, using the paralyzed muscles as much as possible, and make use of the most nutritious and easily digested food. The bowels must be kept regular daily.

Hysterical paralysis requires the Opium and Belladonna plug in the vagina, lying upon the back, with the limbs and head elevated, as stated above, and galvanism; at the same time employing uterine tonics, and ferruginous preparations if anemia be present. Frequently, proper mental influence will remove it. This form of paralysis presents symptoms of hysteria, with cramps, and uterine derangement; it may be located on one side, in the inferior limbs, or effect only a single muscle or joint.

Sometimes there will be an inability to speak above a whisper, which may continue for a longer or shorter time, the proper voice returning suddenly and unexpectedly. The face, and the tongue are not affected in this disease; but in walking, the leg will be drawn along, as if lifeless, sweeping the ground. There will be an absence of any signs of lesions of the nervous centers; the paralysis is incomplete; and the muscles are not wasted; frequently, in yawning or sighing, or under strong emotion, the paralyzed limb will be moved as well as the sound one. It is commonly brought on by exhausting or debilitating causes, as, leucorrhœa, over-work, excessive menstruation, anxiety or excitement, etc.

Infantile paralysis, from dentition, and other sources of irritation, requires a treatment similar to that named for reflex paralysis.

Cutting the gums, if dentition be the cause, using counter-irritation, warm bath, keeping the bowels regular, the paralyzed limbs in warm flannels, and cupping repeatedly in the neighborhood of the origins of the nerves—sometimes dry cupping will answer, at other times wet cupping will be required. Sulphate of Quinia, Tincture of Arnica, and Tincture of Black Cohosh, combined, may be used internally with great advantage. If not promptly removed, it is apt to produce some form of club foot, especially when there is a lesion of the spinal cord, which may be the result of blows, falls, convulsions, acute diseases, or long-continued irritations; sometimes the cause is very obscure, the paralysis coming on when the child is in apparent robust health. It is apt to involve only single muscles or groups of muscles in the extremities, motion alone being affected, sensation remaining perfect or nearly so. Its most severe form is not attended with any danger to life.

Diphtheritic paralysis, or palsy following diphtheria, is another form of reflex paralysis. It usually commences in the pharynx and velum palati, as manifested by the nasal twang and dysphagia, and may extend to nearly all the motor muscles including those of speech and deglutition. Sometimes the voice, tongue, and faculty of swallowing, remain unimpaired. It may commence suddenly, or gradually, with loss of muscular power, formication, tenderness, a doughy, inelastic feel of the affected muscles, but not much atrophy. No apparent organic lesion of the cerebro-spinal or other organs exists, unless they were present before the diphtheria manifested itself. Sensation is ordinarily more or less perfect. The *prognosis* is usually favorable, though sometimes death has occurred suddenly from paralysis of the respiratory muscles, or sudden suffocation, or, perhaps, as a consequence of paralysis of the heart.

The *treatment* consists in frictions to the spinal column and affected muscles, when it can be accomplished without inducing fatigue or exhaustion; lying upon the back once or twice a day, as referred to above, in order to favor the gravitation of blood to the spinal cord; enveloping the body in warm flannels; bathing the surface with a warm Solution of Sulphuret of Potash to augment the action of the skin and capillaries; together with Strychnia in doses of from $\frac{1}{60}$ th to $\frac{1}{30}$ th of a grain, four, five, or six times a day; Pyrophosphate of Iron in doses of from two to five grains, three or four times a day; Xanthoxylin; Alcoholic Extract of Black Cohosh; Tincture of Arnica; Tincture of Rhns Toxicodendron; Tincture of Guaiacum; etc. When the paralysis has been on for some time, and not before, moderate currents of electro-magnetism may be passed every day through the paralyzed parts.

Rheumatic paralysis, like the hysterical, is usually confined to one locality, as the extensor muscles of the fore-arm; the deltoid, and trapezius; interfering with raising of the arm; as well as the interossei and lumbricales muscles. The portio dura may also be affected with the rheumatic disease, giving rise to facial palsy. It sometimes invades quite suddenly; at other times, gradually, commencing with a feeling of numbness in the fingers or toes, rendering their movements difficult and tiresome, which gradually proceeds until motion is rendered nearly, if not quite impossible. In some cases pain is present; in others it will be absent. Electricity is apt to occasion pain in a sudden attack, when the affected muscles are excited by it. Paraplegia is apt to be present when the muscles of the lower extremities are affected; and which must not be confounded with that occasioned by a lesion of the spinal cord. If the disease be allowed to progress without treatment, atrophy of the muscles occurs, the affected parts become cold, and the fingers or toes can hardly be separated from each other, the stiffness and numbness of which increase until the hand becomes useless. Sometimes, with these symptoms of atrophy and contractions, there will also be deposits and a somewhat anchylosed condition of certain joints.

The disease may be *diagnosed* by the previous history of the case, the pain attending the paralysis, and the absence of symptoms indicative of cerebral lesion.

The *treatment* is generally successful if undertaken at an early period; it consists of an energetic and long-continued course of electro-magnetism, aided by the internal use of Strychnia; and subsequently by remedies used in the treatment of chronic rheumatism. Should the muscular tissue become atrophied, there is not so much certainty of cure; still, electro-magnetism will be found of great service, aided by very powerful stimulating liniments over the atrophied muscles.

4. FACIAL PARALYSIS, and other local palsies, are usually due to compression or disease of nerves. The paralysis may be direct or reflex; and occasionally owing to some disease of the brain. Facial palsy is a more common form of local paralysis than any other. There are two different kinds of it; one arising from exposure to a draught of cold air, and generally caused by a rheumatic effusion, which takes place in the cellular tissue, between the facial muscles and the exterior branches of the portio dura, which compresses the muscular and nervous fibers, interfering with their functions. (The same result may arise from otitis or tumors, syphilitic or other deposits, caries, etc., existing some-

where along the course of the nerve, after its exit from the cavity of the cranium.) In this case there is no destruction or inflammation of the nerve, and the paralysis disappears in proportion as the effusion is absorbed; sometimes spontaneously, or by means of proper medicines, with electricity to excite the muscles. An Ointment of Iodide of Potassium frequently affords amelioration, by causing absorption of the rheumatic effusion. In all cases the bowels must be kept regular.

In facial palsy the physiognomical expressions of surprise, terror, hilarity; rage, etc., disappear on the affected side, and are exaggerated on the healthy side; the patient can not laugh, frown, or whistle, and the face will be drawn to one side, or other changes occur in the features, due to the want of equilibrium between the paralyzed and healthy muscles. If both sides of the face are paralyzed, the features are stoical, appearing as if covered by a mask, the eyeballs alone being moveable.

The portio dura or facial nerve being the motor nerve for a number of the muscles of the face, its simple or partial paralysis, (palsy of its superficial branches), may give rise to different results, according to the muscle or muscles affected. Thus, if the frontal portion of the *occipito-frontalis* muscle and the *corrugator supercilii* are paralyzed, wrinkles will disappear from the forehead, which will become smooth, and the patient will be unable to frown or move the scalp. The paralysis of the frontal muscle causes the transverse wrinkles to disappear; while that of the corrugator removes the perpendicular rugosities. In some cases a doleful, or even terrible expression is given to the face, in consequence of a dropping and hanging of the eyebrow over the eyeball.

If the *orbicularis palpebrarum* is paralyzed the eye can not be shut; and in consequence of its being thus constantly exposed to the air, even during sleep, the conjunctiva becomes irritated, giving rise to an abundant flow of tears, which may excoriate the skin of the cheek, over which they pass, from their acridity. The eye appears staring and protruded, and the eyelids are farther apart than natural; the dropping of the lower eyelid exposes a large portion of the sclerotica to view. The eyelids are kept apart, because the levator palpebræ superioris muscle, which is the antagonist of the orbicularis, retains its power, it being animated by the third pair and not by the portio dura. (When the third nerve is paralyzed, the eye remains closed, the patient not being able to open it.) Those changes in the nutrition of the cornea and of the conjunctiva, which occur in paralysis of the fifth pair, (tri-facial, almost wholly a nerve of sensation), are never observed. If the

patient is told to shut the eye, either no motion is observed, or the eyeball is carried upward and inward beneath the upper eyelid so as to partially or wholly conceal the cornea,—from the action of the rectus internus, rectus superior, and obliquus inferior muscles, which are animated by the third pair and not by the portio dura. As paralysis of the orbicularis never occurs in facial palsy arising from intra-cranial injury, when, in a case of facial paralysis, we observe that the eye can not be closed, we may be certain that the paralysis is of the portio dura, and not of cerebral origin.

If the *levator alæ nasi* and *pyramidalis nasi* are palsied, voluntary motion of the affected nostril is lost, and it is kept open only by the rigidity of the nasal cartilages. In respiration, the movements of the nostrils are opposite to those which they have in the healthy state; thus, the nostrils are dilated, during the normal state, while inspiration is going on, and constricted during expiration, but in facial palsy, they become constricted during inspiration by the air rushing into the lungs, and dilated during expiration by the air being driven out of the lungs.

When the *zygomatici* muscles and the *levator anguli oris* are palsied, the mouth is drawn to one side, and the angle of the mouth appears depressed and pendant, while that of the healthy side is higher and drawn toward the corresponding ear.

Paralysis of the deep and large *buccinator* muscle causes the face to have an aged appearance, the cheek appearing very flaccid, and hanging loosely. The cheek becomes depressed during inspiration, but during expiration, as it can not resist the pressure of air, it becomes distended and swollen, producing movements similar to those made in smoking a segar which “does not draw easily.” As the temporal and masseter muscles are animated by the trigeminal nerve, and not by the portio dura, mastication is usually not much interfered with, though it is very annoying from the food accumulating between the jaw and the cheek. In drinking, some of the fluid escapes at the corner of the mouth; and the looseness of the cheek interferes more or less with the speech.

Paralysis of the *orbicularis oris* prevents the patient from “puckering” up his mouth, so that he can not whistle. The muscles on the sound side draw the lips toward their corresponding ear, causing them to appear longer, and giving more prominence to the naso-labial sulcus; an involuntary flow of saliva takes place, and the labials are pronounced with the greatest difficulty, if at all.

In addition to the measures recommended above for this form of facial palsy, the following have been frequently used with efficacy:

1. Take of Extract of Hyoscyamus half a drachm, Sulphate of

Morphia three grains, Strychnia two grains, Capsicum half a drachm, Sulphate of Zinc fifteen grains; mix; divide into thirty pills, and administer one for a dose, repeating it three times a day.

2. Extract of Hyoseyanus half a drachm, Valerianate of Zinc one scruple, Alcoholic Extract of Black Cohosh one drachm; mix; divide into thirty pills, and administer as the preceding.

3. Take of Phosphorus one grain, dissolve it in Dippell's Animal Oil one drachm, Oil of Cloves twenty grains; dose; three drops on a piece of sugar every night and morning, to be gradually increased to twenty drops. In addition to this rub the affected parts with the following: Take of Phosphorus two grains, Dippell's Animal Oil one drachm, Cajeput Oil half a drachm; dissolve together.

4. Take of Strychnia one scruple, Aconitina four grains, Alcohol, seventy per cent., half a fluidounce, Ointment of Iodide of Ammonium one ounce; dissolve the Strychnia and Aconitina in the Alcohol, and then triturate the solution thoroughly with the Ointment. Used as a local application over the affected muscles.

5. Compound Tar Plaster to the mastoid region of the affected side, and the internal and external use of Strychnia. Strychnia in small doses, combined with Belladonna and Alcoholic Extract of Black Cohosh, may be given internally; and as a local application the following: Take of Strychnia three grains, Alcohol one fluidounce; dissolve—apply from half a drachm to a drachm to the cuticle of the affected part, aiding its absorption by friction, and repeating it three times a day.

6. Steaming the affected part over the vapor from an infusion of stimulating herbs, has sometimes proved successful.

The other form of facial paralysis is due to injury of the intracranial portion of the facial nerve. In addition to the symptoms already named, but which are more general and uniform, there will be a loss of taste, numbness in the tongue caused by paralysis of the *chorda tympani*; difficulty of swallowing; caused by paralysis of those branches which animate the *digastricus* and *stylohyoideus* muscles; the hearing is more or less affected, and the uvula deviates toward the healthy side. In some cases the patient may move the tongue, but not so as to cover the upper lip with it, so as to have its tip touch the nasal septum. Paralytic affections of the tongue and the pharynx ought to arouse our suspicion, as they are generally due to cerebral disease. Double vision, ptosis, dilatation of the pupil, presbyopia, and strabismus may also be present, but these symptoms are not necessarily owing to brain

disease, as they are frequently the result of rheumatic, or syphilitic affections, improper use of the muscles of the eye, etc.

In this form of facial paralysis the intra-cranial cause of the disease must first be remedied, before any local measures be taken to remove it. The application of galvanism, or stimulants to the paralyzed parts, will not only be useless, but will be apt to increase the cerebral malady. In all cases which result from injury to the trunk of the portio dura, benefit can only be expected from galvanism or electro-magnetism, when the original lesion has nearly or wholly subsided; if the continuity of the fibers of the facial nerve has been quite destroyed the palsy is incurable—as well as when there is a permanent contraction of the paralyzed muscles. In advanced age a cure is doubtful, in both forms of facial paralysis. As soon as the nerve has nearly or fully regained its normal condition, by treatment directed to the intra-cranial difficulty, if this can be determined, then the palsy may be cured by a continuance of such treatment, aided by that advised under the preceding form of facial paralysis. Frequently facial palsy of intra-cranial origin will prove incurable.

5. SCRIBES' PALSY, also called "Writers' Cramp," "Scriveners' Cramp," "Sempstresses' Palsy," etc., is a peculiar affection, sometimes met with among writers, painters, cutters, carvers, sempstresses, sculptors, and those whose daily occupation requires the use of the fingers in a more or less flexed condition, with, at the same time, a greater or less degree of pressure upon the nervous filaments supplying the finger's ends, especially those of the thumb. It may also be occasioned by injuries of the radial or ulnar nerves, rheumatism, etc. Some cases appear to be wholly spasmodic, the fingers, and especially the thumb, being strongly flexed into the palm of the hand whenever the patient attempts to write, paint, etc. In other cases it is a paralysis of the short extensor muscle of the thumb, the adductor of the thumb, and abductor of the forefinger: the hand can not hold the pen, or brush, etc., steadily, and the fingers slip away from it. The muscles cease to obey the will.

The *symptoms* usually observed are, an entire or partial loss of sensation at the end of the thumb and index finger of the right hand, and, with loss of power to hold the pen, brush, needle, etc. Occasionally the finger and thumb of the left hand are similarly affected, especially, when the disease is caused by an injury or rheumatism. Sometimes every other movement of the hand, save that of writing, sewing, etc., however minute, is perfectly retained. The fingers affected, frequently diminish in volume,

and more or less rapidly lose the power of contraction. The muscles especially affected are the *opponens pollicis*, the *flexor brevis* and *adductor pollicis*, the first two *lumbricales*, and the *abductor indicis*. At the same time the skin of the palmar surface of the thumb and index fingers, especially at their tips, becomes insensible; and the *anæsthesia* frequently also affects the middle finger. This paralysis rarely appears suddenly. There is first cutaneous *anæsthesia*; then the electro-cutaneous sensibility is diminished or abolished, and the electro-muscular contractibility more or less diminished. Most of the patients experience some uneasiness in the lower part of the cervical region, and in the upper part of the dorsal; and many medical men believe that the disease commences in the spinal cord.

Frictions and liniments are of no service in this disease. Mechanical support affords much relief, and may enable the patient to write, etc., but ultimately, even with this, the extensor muscles of the thumb become so weak that the support fails to continue its benefit. But mechanical support, aided by electro-magnetism will effect cures. M. Duchenne, has used the following apparatus with success: place over the affected thumb a finger of a glove, and on the fore-arm of the affected side lace a sleeve of copper. A loop attached to this glove finger at the level of the posterior extremity of the thumb, slides in a groove going along upon the posterior face of the articulation of the first and second phalanges, then it passes up again obliquely on the external side of the thenar eminence, in order to come out of the sheath at the level of the superior attachment of the *abductor* muscle of the thumb. In drawing upon this loop, the first metacarpal executes its motion of opposition, the last phalanx of the thumb becomes extended, and the first inclines laterally so that the thumb is opposed to the first two fingers. This is the proper action of the *abductor* muscle of the thumb. To put this artificial *abductor* muscle in operation, its free extremity is attached to a spiral spring, which is fixed to a button fastened on the anterior face of the copper sleeve, and by which the tension is graduated. This is especially useful where there is an atrophy of the muscles of the thenar eminence.

A still more simple apparatus has been devised by M. Duchenne; it consists of a tube of vulcanized caoutchouc, which embraces the superior extremity of the first metacarpal, in the fashion of a ring, and passes up again obliquely toward the internal border of the wrist around which it is rolled. The caoutchouc is stretched more or less, the fore-arm being preserved from compression by a copper sleeve. Its inconveniences are: it has a slight action of extension

on the last phalanx, and, by exerting a circular compression on a very limited point of the thumb, it interferes with the circulation. These are by no means expensive apparatus. "Perry's Orthodactylic Pen-holder," has proved serviceable in many cases where the patient was compelled to continue his writing.

When the disease is spasmodic, a constant continuous current of galvanism should be applied daily to the flexor muscles. Complete and absolute rest of the palsied hand for two or three months, upon the first appearance of the disease, should always be advised; after which period, electricity, strychnia, etc., will prove serviceable. If employed at too early a period, strychnia is apt to prove injurious. Sometimes the disease, in either form, is unyielding to any treatment.

6. PARALYSIS AGITANS, "Shaking Palsy," or "Trembling Palsy," is a disease frequently met with, and appears to be more common among males during middle and advanced age. It is characterized by a constant involuntary shaking or trembling of one or more parts of the body, with diminished muscular power. Its *causes* are not well understood, having been attributed to muscular exhaustion, feebleness of nerve power, chronic disease of the superior portion of the spinal cord, the tubercula quadrigemina, or of the medulla oblongata, etc. Sometimes it has followed chronic rheumatism, as well as severe exposure to cold and dampness.

The approach of this malady is generally so imperceptible that the precise period of its commencement is seldom recollected by the patient. A slight sense of weakness, with a proneness to trembling, sometimes in the head, but more commonly in the hands or arms, are the first symptoms noticed. These affections gradually increase, the patient bends himself forward, and, by degrees, the legs suffer similar agitations, and there is a loss of power with the hands and arms. As the disease advances, the limbs become less and less capable of executing the dictates of the will, while the patient seldom experiences even a few minutes suspension of the tremulous agitation; and should it be stopped in one limb by a sudden change of posture, it soon makes its appearance in another. This condition of symptoms may continue for years, but gradually augmenting in severity.

In the far-advanced stage, the tremulous motions of the limbs occur during sleep, and increase in violence until they waken the patient in much agitation and alarm; the power of conveying food to the mouth is impeded; the bowels are exceedingly torpid; the trunk is permanently bent forward; muscular power diminished; articulation at length becomes indistinct; mastication and swallow-

ing difficult; and the saliva constantly dribbles from the mouth. The mental faculties may remain unimpaired for some years, but at length, as the symptoms increase, drowsiness, delirium, and marks of exhaustion, or coma, precede death.

Shaking palsy, in some respects, resembles *chorea*, but may be distinguished from it by its peculiar symptoms, and by its attacking those in mature and advanced age. *Chorea* almost invariably attacks the young.

The *treatment* of paralysis agitans has occasionally been successful, especially in its earlier stage; but in its advanced period it is incurable. Any cerebral or spinal disease which may be suspected to exist, must be met with the Iodide or Bromide of Potassium, or Ammonium; Compound Tar Plaster; and the means advised for such diseases. Internally, to give tone to the nerves and muscles, the following may be administered: Take of Sulphate of Quinia twenty grains, Elixir of Vitriol two fluidrachms, dissolve, and add Tincture of Black Cohosh two fluidounces. The dose of this is forty drops, three or four times a day in a little water. Pyrophosphate of Iron, or Elixir of Iron and Cinchona may be used in addition. The continuous direct galvanic current should be carefully applied to the affected parts, for from half an hour to an hour at a time, daily; followed by soothing, gentle frictions with the hand; after which the parts should be kept warm by covering them with flannel or fur. The bowels, skin, kidneys, etc., should be attended to; diet be nutritious and easy of digestion; the mind should be kept as free from excitement as possible; coition must be avoided; and as little exercise as possible should be taken, and, always of a passive character.

7. PARALYSIS *affecting the co-ordinating power, Tabes Dorsalis, Ataxie Myelo-phthisis, or Ataxie Musculaire Locomotrice* of Duchenne. This is a peculiar affection, the characteristic features of which are, "progressive abolition of the co-ordination of movements and apparent paralysis, contrasting with the persistent integrity of the muscular forces."

Duchenne, in his work entitled "*Electrization Localisée*," Paris, 1861, gives the following description of the disease: "Persons affected with it present a group of phenomena which are identical; the commencement, the symptoms, the progress, and the termination of the disease are the same. Paralysis of the sixth pair or of the third pair, a feebleness, or even complete loss of sight, attended with inequality of the pupils, are the symptoms present in a majority of cases, either at the commencement, or are the forerunners to the derangement of the co-ordination of movement.

Very peculiar pains of a piercing character, shifting, erratic, quick as lightning but of slight duration, very similar to electric shocks, reappearing in paroxysms, and attacking all the regions of the body, are present with these paralyses, either accompanying them, or appearing subsequently; and these form the first stage of the disease. The second stage comes on after an interval of several months, or even several years; there is vertigo; difficulty of keeping the body in equilibrium; sooner or later there is a diminution or entire loss of the sense of touch, as well as of the sensibility to pain, especially in the inferior extremities, rarely in the superior; and in the third stage the disease becomes general.—During the progress of the affection, the rectum and the bladder are frequently deranged, but no sugar or albumen exists in the urine; the intellect is undisturbed; there is no embarrassment nor hesitation in speech; electro-muscular contractility remains undisturbed; there is no alteration of nutrition in the muscles, no morbid changes in their tissue; and the disease is not only liable to become general, but often proves fatal.” (*Duchenne.*)

“The loss of power of co-ordinating the movements which is manifested in the lower extremities, consists in a difficulty of maintaining an erect position without trembling, or without support, or of performing certain movements in progression, such as lateral or gyratory movements. At such time the patients commonly feel giddy, and as if about to lose their balance, and sometimes think that their lower extremities have lost their power;” (if the patient close his eyes, it augments the uncertainty and unsteadiness of his gait, so that he can not stand erect with his feet together without immediately losing his balance, or, can not take a step forward without falling—*Trousseau*); the tactile sensibility of the sole of the foot becomes blunted or otherwise altered. They soon seem to be walking on soft substances when treading upon a pavement, or the ground appears to be elastic and to jerk them up. Subsequently they are unable to walk without throwing the legs forcibly forward and striking the ground violently with the heel. These movements are at times so violent and sudden that the body is shaken at every step, and the patient loses his balance; this irregularity increases to such an extent as to render standing and walking almost impossible. It is then necessary to support the individual on both sides, and in attempting to make a few steps, his limbs will be agitated in the most violent manner, without apparent object; the strength is speedily exhausted by these efforts, and he begs to be led back to his arm-chair. In this condition the patients pass their lives, sitting or lying down. At the same time,

with all these symptoms of paralysis, there is great force in individual movements, as shown by a dynamometer invented by Dr. Duchenne." (*Brit. and For. Med.-Chir. Rev.*, April, 1859.) Upon attempting to flex the patient's leg or extend it against his will, he will be found to have a natural degree of muscular power, or, at all events, more than is met with in other forms of paralysis.

The *causes* of this disease are not understood; it has been attributed to sexual excesses, and there is no doubt but that this may give rise to it,—but then, it has occurred where the patients were extremely continent, or moderate in their sexual contacts. It affects both males and females, and may occur at any period of life from the development of puberty to the forty-fifth year; and, according to Trousseau, and Friedreich, it may be transmitted from parent to child, or rather, families of a strongly-marked tendency to nervous diseases are liable to it, several members of one family having been known to labor under it. A writer states that anatomically, the malady is "a chronic inflammatory process, resulting in the atrophy of the nerve elements, and which, being confined to the posterior column of the spinal cord, begins in its lumbar region and gradually extends thence both upward and downward. With this alteration is associated a spinal meningitis affecting the posterior face of the cord, and proportioned in its degree to that of alteration of the cord itself." I have recently witnessed a case of this disease in a confirmed onanist; the patient is still living, but is now constantly confined to his bed. Five years ago he called upon me, and from his gait, I at first considered him under the influence of liquor. I did not treat him, as I considered his case, even then, hopeless.

The *diagnosis* of the disease is not very difficult; it may be determined from any of the other forms of paralysis, not only by the staggering gait of the patient, or his inability to walk without support, from the muscles not being under the control of the will, but also by the presence of muscular power, which is not lost as in the other paralysees. There are no tremors, no thickness of speech, no loss of the power of muscular movement, no want of contractility under the electric stimulus, no fatty degeneration of the muscles, and no dementia, as is the case with general paralysis.

The *prognosis* of this disease is almost invariably unfavorable. The amaurosis, strabismus, piercing pains, in the lower extremities, etc., indicative of the first stage will frequently be found wanting, and the first symptom observed will be the peculiar characteristic of the disease, viz.—the imperfect power of co-ordination of the muscles of the inferior limbs, and occasionally of other

parts; and when this is present, the disease has passed far beyond its initial period. It may exist alone, or be complicated with morbid conditions of the gray matter, and of the lateral or of the anterior columns of the spinal cord, giving rise, in addition, to more or less hyperæsthesia, anæsthesia, and true paralysis. The disease is usually of long duration, lasting a number of years. Almost all remedial agents and compounds have been recommended and tried for this disease, but without the least benefit. Friedreich says: "It is indeed discouraging to observe, how, in spite of active remedies, the symptoms gradually but visibly grow worse, while an evident suspension of its rate of progress may be observed when all medicines are discarded and the patient is confined entirely to dietetic measures." Romberg, who has also given much attention to the malady, observes: "There is no prospect of recovery for patients of this class; the fatal issue is unavoidable; the only consolation that can be offered to those fond of existence is the long continuance of the disease. If, in any case, the busy activity of the physician increases the sufferings of his patient, it is in *tabes dorsalis*."

The *pathological appearances* in those who have died while laboring under this malady, are almost uniformly the same, viz.: a degeneration of the posterior columns of the spinal cord, and, in some cases, also of the cineritious substance, which exhibit a grayish-yellow and semi-transparent appearance; the posterior roots of the spinal nerves are atrophied, thinner, flatter, and harder than natural, and of a reddish-gray color, especially those in the lumbar region. Fluctuation may frequently be detected in the lumbar region, and if the membranes in this location be opened, there will be a discharge of clear, transparent fluid. The pia mater may be firmer than usual, more closely adherent to the substance of the cord, of a dirty-white appearance, and having many white bands of various sizes upon its external surface connecting it to the internal face of the dura mater. Thickening and milky opacity of the ligamentum denticulatum. Sometimes the optic nerve will be altered, and even the tubercula quadrigemina. Along the posterior surface of the spinal marrow a depression or groove, of varying depth will be found, being deepest in the lumbar and dorsal regions, and which depression corresponds to the atrophied posterior columns. The affection appears to commence at the lumbar region, where the greatest changes will be observed, and extend thence in either direction, up or down. The microscope will detect the atrophy wherever the posterior column presents a grayish color: no normal nerve fibers, or but few, can be found,

their place being occupied by slender empty tubes, surrounded by a substance composed of cells with one or more nuclei, and granular matter. Fatty degeneration is entirely absent. Brown-Sequard, who has closely investigated this disease, states that it may arise from many spinal affections; and this is, no doubt, correct.

Treatment in this disease has effected absolutely nothing. Wunderlich, Charcot and Vulpian, and Herschel, have related cases benefited by the internal use of Nitrate of Silver, in doses of one-fifth of a grain, given night and morning at first, and after a while, three times a day; its good effects are stated to manifest themselves in from six to twenty days. Probably, in the commencement of the disease, whenever it can be diagnosed, the use of the Hypophosphites, in conjunction with Bromide of Potassium, or, of Ammonium, and Extract of Conium, stimulants to the lumbar and dorsal region, moderate exercise in the open air unless the symptoms contraindicate it, and a moderate but nutritious and easily digestible diet, may prove beneficial; and Nitrate of Silver may also be tried. But after the symptoms of impairment of the co-ordinating faculty have appeared, it is doubtful whether confidence can be placed in any treatment. Dietetic measures appear to answer a better purpose than therapeutic; although I should perseveringly continue the use of Hypophosphites, Bromides, etc., above referred to, for several successive years.

M. Carre d'Avignon, who has presented the medical world with a very excellent monograph upon the anatomy, physiology, etc., of this disease, suggests a mode of treatment by subcutaneous injections of Solution of Nitrate of Silver along the vertebral column, and especially over the track of the painful nerves. This determines at such points a substitutive inflammation, the first effect of which is to calm the pain,—the second to diminish the incoordination. He believes that this agent produces a modification in the nerves in the vicinity of the solution, that this modification extends along the sensitive track of the nerves to the posterior columns, determining in their interior a particular perturbation which arouses its vitality, and favors the resorption of the morbid products and the reparation of the elements. He prefers to act upon the intercostal and sciatic nerves, and uses from ten to twenty drops at a time. Belladonna may be given internally at the same time.

8. **HEMIPLEGIA** is paralysis of one side, or of a lateral half of the body, and is generally due to disease of the brain. It may, however, be caused by an external irritation, and form a reflex paralysis; and it is not unfrequently a result of epilepsy, which may

produce an exhausted condition of the deep-seated white substance of the brain, as the optic thalami, and corpora striata, very much resembling the condition of white softening. Hemiplegia may also be congenital, or occur soon after birth, depending upon some cerebral deformity or deficiency; of course, it is then incurable.

Hemiplegia is the most common variety of paralysis met with, and is most commonly associated with apoplexy either following or preceding it; yet it often occurs without any loss of consciousness, either at the time of its supervention or afterward. It may attack at any period of life, but more commonly after the fortieth year of age. (*See Softening of the Brain, and Apoplexy.*)

The cause of hemiplegia, independent of injury and outside irritation, is the same as that of apoplexy; that is, tumors or softening of the brain, and cerebral hemorrhage, and an attack may be induced by the same exciting causes.

Spinal hemiplegia is of rare occurrence, and is commonly the result of lesion of the cord immediately below the decussation of the anterior pyramids, the lesion being confined to only one-half of the cord; a very prominent symptom in spinal hemiplegia is the implication of the intercostal or abdominal muscles, which is present in genuine hemiplegia only when the cerebral lesion is extensive. The paralysis is also apt to affect first a shoulder or an arm, and then more or less gradually extend itself. The mental faculties are rarely, if ever, impaired, unless a cerebral lesion be associated with the spinal. The limb first attacked, usually the leg, is more obstinately affected than the other one, or arm.

The *symptoms* of hemiplegia are readily made out; there is a want of motion of exactly one-half of the body, more commonly of the left side. The attack may occur gradually, at first appearing as a local palsy, either in the fingers or toes, which gradually extends itself until the whole of that side of the body is involved. Again, we frequently observe persons of advanced years attacked with hemiplegia, after having suffered for some time with symptoms indicative of cerebral disorder. When the attack is sudden there is at first, in nearly all cases, a loss of both motion and sensation, but the latter function returns, to a greater or less extent, after a longer or shorter period. In a severe attack, the muscles of the face are involved, the corner of the mouth being drawn toward the ear of the affected side, and the tongue is also paralyzed, rendering speech very imperfect and difficult, and when this organ is protruded its point is turned toward the affected side. There is often an appearance as if the cheeks were hang-

ing, and not supported properly by their muscles; but the face is not always palsied. Although the fifth pair is generally implicated in the paralysis, yet it is frequently the case that the portio dura remains free. The affected parts are often cold, and somewhat swollen, with more or less impairment of sensation; the circulation is slow, and the mind is more or less affected.

The paralysis, when due to cerebral disease, is on the side opposite to that of the mischief in the brain. Dr. Mayo gives the following explanation: "The fibers of the anterior pyramids pass through the pons Varolii. The pons Varolii consist in great part of filaments which issue from each hemisphere of the cerebellum. These filaments may easily be supposed to convey a depressing influence from the diseased hemisphere. But in their course they come immediately upon the filaments of the anterior pyramid of the same side; and they are so implicated with the latter, with such a singular closeness of reticulation, and often with so much that looks like an actual interchange of filament, that it is far from unlikely that they may transmit to the descending fasciculi of the pyramid, a shock which may thence be communicated to the same part at which a *cerebral* lesion exerts its paralyzing force."

Andral has observed that when the blood is effused into one side of the cerebellum, and no where else, the paralysis takes place in the limbs of the opposite side of the body. But if the effusion occur simultaneously on one side of the cerebellum, and on the other side of the cerebrum, instead of having a double palsy or general paralysis, more commonly the cerebral affection overcomes that of the cerebrum, and the paralysis occurs on the side opposite to the lesion in the brain proper. It, therefore, appears that a lesion above the decussation of the pyramidal column gives rise to paralysis on the opposite side; if it be below the decussation, the paralysis is on the same side; and if it be on the same plane with the decussation, there will be paralysis on both sides. If motion be greatly palsied, the lesion has involved the corpus striatum: if sensation, the optic thalamus. Though frequently, both of these bodies may be involved in the disease, at the same time.

The premonitory *symptoms* of hemiplegia are the same as those in Apoplexy, and Softening of the Brain, *which see*.

The *diagnosis* of hemiplegia is readily made out; but the exact seat of the lesion giving rise to it is by no means easy of determination. In a practical view, however, it is of more importance to understand the probable nature than the exact seat of the lesion. There are, unfortunately, no very certain means of diagnosis

between hemiplegia from effusion of blood, and that from white or non-inflammatory softening.

When coma attends a sudden attack of paralysis, this is due to an apoplectic effusion; if no coma be present, it is generally indicative of a quick breaking down of a softened brain. If the paralysis comes on gradually, it is due to some chronic cerebral lesion, as, ramollissement, tumors, etc. When hemiplegia is complicated with disease of the heart, of the arteries, or of the kidneys, the palsy may be occasioned by softening, cerebral hemorrhage, or by a fibrinous clot plugging up a cerebral artery. (*See Diagnosis of Softening of the Brain.*)

According to Dr. Todd, early rigidity of the paralyzed muscles is evidence of irritative disease within the cranium; late rigidity following complete resolution of the muscles indicate that there has been loss of substance in the brain, and that the cicatrix is undergoing contraction. He also admits that galvanism or electro-magnetism may serve as a test to distinguish between an irritant and a depressing lesion of the brain, but not as a means of distinguishing between cerebral and spinal palsy. If the muscles of a paralytic limb are, by a current of the same intensity, more powerfully convulsed than those of the sound side, we may fairly conclude that the paralysis is due to brain disease, and that the lesion is of an irritative character. But the excitability of the muscles is by no means augmented in *all* cases of paralysis resulting from a lesion of the brain; in some cases the galvanic stimulus produces an augmented excitability of the paralyzed muscles, greater than that produced in the opposite healthy muscles, together with some degree of rigidity. In a second class of cases, the stimulus produces little or no contraction; the muscles being more or less wasted, soft, and flaccid. In this class there appears to be no longer any intercranial irritation; the seat of the paralysis is no longer in the brain, but in the muscles which are impaired by the long rest they have necessarily taken after the attack,—paralysis from disuse,—and electric treatment will be useful. In a third class of cases, usually observed in cases of apoplexy occurring in persons previously healthy and not advanced in years, the paralysis may be almost complete, yet the galvanic stimulus will equally excite the muscles of the paralyzed and those of the healthy limbs.* (*See Diagnosis of Lead Paralysis.*)

* The British Medical Journal, 1861, p. 230, gives the following abstract from one of Dr. Brown-Sequard's Lectures on Diseases of the Base of the Encephalon:

"A very important observation has been made—that all the nerves entering

Dr. Gull states that "if a disorganization of the brain exists, whether affecting the anterior or posterior cerebral lobe, involving the optic thalamus, or corpora striatum, singly or equally, then there will be a greater affection of the upper than of the lower extremity,

the brain through the base of the skull decussate near their entrance into the encephalon; and after the decussation, most of them send fibers upward into the brain. Knowing this we may first determine theoretically what symptoms should be produced by injury of a given part; and then examine how far this theory of symptoms agrees with what is actually observed.

"With the exception of the auditory nerve, the cranial nerves springing from the *medulla oblongata* have their origin at the back rather than at the front of this part of the encephalon. All these nerves pass into the gray matter, and there undergo partial decussation. To illustrate the effects of disease on these, according to its seat, the lecturer selected the sixth nerve.

"Diseases affecting the medulla just at the origin of the sixth nerve on one side will produce paralysis of the external rectus on the same side as the injury; while there will be paralysis of the opposite side of the body. This agrees with what is observed in practice. But if it be inflammation that affects the origin of the sixth nerve, there will be convulsive action of the muscle supplied by it, and the eye will be drawn outward. Again, if this nerve be injured after its decussation in the pons Varolii, the external rectus of the other side is paralyzed; and the paralysis of the muscle of the eye here occurs on the same side as the general paralysis of the body and limbs. In another class of cases there may be an injury to one side, small in extent, yet near enough to the point of decussation to affect the nerves on both sides. Here there will be paralysis of both external recti, although one side of the body is paralyzed.

"Analogous phenomena are observed when other of the cranial nerves are affected. The phenomena of 'alternate paralysis,' (paralysis partly affecting one side of the body and partly the other), have lately been made the subject of a paper by M. Gubler. M. Brown-Sequard, however, had given an explanation of the fact ten years ago; and even then he did not think he was advancing any new doctrine. The phenomena had also been explained by Romberg and others prior to the appearance of M. Gubler's essay. M. Gubler has collected cases of injury at the *lower part of the pons Varolii*, affecting the facial and trigeminal nerves, and producing paralysis of the parts supplied by these nerves on the same side; while the opposite side of the body has been paralyzed. It would appear, however, that M. Gubler has drawn too general a conclusion from these facts; for if the injury be at the level of the decussation of the nerves, then the paralysis of the parts supplied by them occurs on both sides. Two cases of this kind have been recorded. Again, injury of the pons above the point of decussation of these nerves will produce paralysis of the face on the opposite side—on the same side as that on which the general paralysis of the body occurs.

"The effect of injury of the pons Varolii in producing paralysis of the cranial nerves then varies according to its situation. When the injury is below the point of decussation, the paralysis is on the same side; when it is above, the paralysis is on the opposite side; and when it is between these, so as to affect the nerves just where they decussate, the paralysis of the parts supplied by the nerves involved, occurs on both sides. Are, then, these signs sufficient for the positive

and a greater loss of motion than of sensation. If there is complete paralysis of both the upper and lower limbs, the lesion having been sudden, the leg will be the first to improve, so that the patient may even be enabled to walk, the muscles nearest the body taking on healthy action the first, and so descending toward the toes; and if sensation and intelligence have been lost, they will return after a few days. He also states that when the third nerve is involved in the hemiplegia, the nerve on the same side as the cerebral lesion is the one that is palsied, the greatest dilatation of the pupil being on that side, vision lost, eyes directed *from* the side affected with palsy, and ptosis on the side opposite to the hemiplegia."—When the

diagnosis of paralysis originating in injury of the pons Varolii? No; but there are other symptoms which aid in the diagnosis.

"If the injury of the pons be produced rapidly, as by effusion of blood, the *breathing* will soon be affected. Again, in the paralyzed parts there is a remarkable *diminution of temperature*; and, as a general rule, the presence of an irritation in the pons, and perhaps in some part of the medulla oblongata, is denoted by a considerable *loss of heat on one side of the body*. If, however, there be *no* irritation the temperature in the paralyzed limbs will be increased. Again, if there be *paralysis of the muscles of the eye*, attended with *constriction of the pupil*, there is an irritation somewhere; and, if there be no other obvious source for this, it must be located in the pons. Further, in most cases of simple injury of the pons, the intelligence remains *normal*; and there is *difficulty in deglutition*, and in the *motion* of the tongue. It is remarkable, however, that it is only when the lower part of the pons Varolii is injured, that the function of the hypoglossal nerve is much impaired.

"The small size of the *anterior pyramids* in the medulla oblongata at first sight renders it difficult to believe that they are the main channel of the motor fibers in their passage from the brain to the spinal cord. Yet injuries of the other parts of the medulla *do not paralyze*; while an injury of the anterior pyramid of one side produces complete paralysis of motion of the opposite side of the body. Pathological facts also show that these anterior pyramids are the continuation of the lateral columns of the cord, and that a decussation takes place in them; for injury of the anterior columns of the cord just below the pyramids does not produce paralysis, while an injury of one lateral column produces paralysis of the body on the same side. The fact of a decussation of motor fibers in the anterior pyramids is also shown in the result of injury of the pons Varolii. If decussation of the nervous fibers did not take place before their entrance into this part, then injury of one side of the pons ought to produce paralysis of the same side of the body; whereas the contrary occurs, as has been shown in sixty or seventy cases.

"The symptoms of irritation in the pons and medulla often manifest themselves in the form of convulsions. But it does not follow, because the convulsions may be epileptiform, that the actual seat of epilepsy is here. The medulla is only the starting point of an irritation; the seat of the epilepsy may vary. The first convulsions are observed to occur sometimes in one and sometimes in another muscle; and occasionally the first result of the irritation is contraction of the blood-vessels of the brain, producing loss of consciousness."

hemiplegia is due to an obstruction of the cerebral arteries, consciousness is usually present, and gangrene of the extremities, renal disturbance, or splenic lesion soon follow.

We must also distinguish cerebral hemiplegia from the hysterical, in which the face is seldom paralyzed, and the patient drags the leg along in walking, instead of bringing the foot in a more or less circular direction; hysteria, and symptoms of uterine derangement will also be present. Sometimes a painful and incomplete hemiplegia will be occasioned by rheumatism, though it must be remembered that brain disease may also be a cause.

In congenital hemiplegia and in perfect paralysis occurring after apoplexy, the *prognosis* is unfavorable, as an entire cure is impossible; the milder and the less sudden the attack, the more favorable is the case; although perfect recovery rarely takes place when the disease is due to organic cerebral lesions. Occasionally a return of motion and sensation, with a sense of warmth in the affected parts, a slight prickling pain, a slight stinging or crawling sensation, is a favorable indication—but not always. Atrophy of the muscles and coldness of the parts are unfavorable symptoms. All these indications are, however, more unfavorable when accompanied with mental disturbance, or some general derangement of the system. Usually, in paralytic attacks, there is a slow but gradual and imperfect amendment, in which the patient may remain for some months or even years, if proper care be adopted, and ultimately die suddenly from apoplexy, or from some other disease. In all cases of hemiplegia the physician should never give positive assurance of perfect recovery, for sudden deaths often occur, even when we believe the case is about to terminate favorably. And in cases where any benefit is expected from treatment, it can only be attained by regular, judicious, and well-conducted measures, faithfully persevered in for months and even years.

The *pathological appearances* met with in hemiplegia are similar to those observed in softening of the brain and apoplexy, as white softening of the optic thalamus and corpus striatum; softening of the convolutions of the anterior lobe; perhaps the blocking up of a cerebral artery, from a clot or chalky deposit, etc., as the mere deprivation of blood has been known to cause hemiplegia—often preceded by coma with more or less snoring; bloody or serous effusion; extravasation of blood into the pons Varolii, perhaps disintegrating the whole of it; more or less fatty degeneration of various parts of the brain, etc.

The *treatment* of hemiplegia, when not due to cerebral disease, will be similar to that of reflex paralysis; first removing the cause, or the external irritation, and then employing tonics and nervines to restore nervous and muscular power, aided by galvanism or electro-magnetism.

When the disease is of brain origin, and which is much more frequently the case, the treatment will greatly depend upon the peculiar characters of the affection, and the length of time that has elapsed since the commencement of the attack. If the hemiplegia is approaching in a gradual manner, the means named under softening of the brain and apoplexy, preventive, therapeutical, and hygienical, together with the application of electro-magnetism to the palsied muscles only, will be the proper ones to pursue; bearing in mind that the Compound Tar Plaster, which should be placed over the occiput and nape of the neck, must be omitted whenever it gives rise to any considerable depression.

In the early period of a sudden attack of this disease, and when symptoms of irritation or hyperemia are present, as known by pain, tenderness on pressure upon the occiput, flushed face, confusion of mind, great drowsiness, or excessive restlessness and wakefulness, and the muscular contractility referred to above, when speaking of the diagnosis,—the treatment must be prompt and energetic. The patient should be kept as quiet as possible in the horizontal position, when not pursuing any of the measures hereafter named, and measures should be adopted to lessen the frequency and force of the heart's action; in order to prevent the blood from escaping from the ruptured vessels, and at the same time not to obstruct the flow so as to interfere with the heart's action, the head should be somewhat elevated, but not too much so; and all cravats, or other ligatures presenting impediments to the free circulation of the blood, must be removed. A stream of warm water should be poured upon the back part of the head and neck of the patient, for about three or four minutes at a time, repeating it two or three times a day; to effect this, the patient's head, kept somewhat elevated, should be brought over the edge of the bed, and be held by an assistant while the warm douche is used, the water being caught in a tub placed on the floor below the head. In some cases, the patient may lie upon his abdomen while this is being done, but in most cases it will be preferable to have him lying upon his side—first one side and then the other—being careful not to worry or fatigue him too much in the operation. Of course, this must be at once omitted, if it gives rise to any unpleasant symptoms; it is superior to the cold douche, being

followed by less energetic reaction, while at the same time it invites a flow of blood into the capillaries of the parts exposed to its action, and also lessens vascular fullness of the internal vessels by its relaxing influence. This having been accomplished, an active purgative injection should be administered, using the same care not to fatigue the patient, and when the alvine discharge occurs, he should not be allowed to rise for its evacuation, but must positively make use of a bed-pan. This aids in removing accumulations in the lower bowel, and also acts as a derivative; and it should be repeated every day. Where the injection fails to act, and the patient is not too greatly prostrated, a purgative may be administered internally, as, a drop or two of Croton Oil placed upon the tongue, or a dose of Podophyllin and Bitartrate of Potassa. If the action of these agents gives rise to prostration, stimulants must be cautiously used, as, Ammonia, Ether, Camphor, etc.

Dry cups to the occipital portion of the cranium, and to the nape of the neck, or even cupping with scarification, when carefully put into use, will often prove advantageous.

Internally, Tincture of Gelsemium, of Aconite, of Veratrum, etc., may be used for the purpose of diminishing the heart's action and producing a tranquil state of the mental and physical system. The kidneys should be watched, employing diuretics should it become necessary, and being careful not to allow the bladder to retain the urine for too great a length of time. And this course should be pursued until the patient is relieved of all the irritating symptoms, varying them as the urgency of the case, or the symptoms may require. The diet should be light, nutritious, and easy of digestion. Galvanism or electro-magnetism is improper, and should never be employed in any case where there are symptoms of cerebral irritation, and augmented excitability of the paralyzed muscles.

But the chronist will rarely be called upon to treat these cases; it will more commonly be among those patients with whom there is a gradually-approaching hemiplëgia, or with whom the hemiplegia is of long standing, that his services will be required. The gradual attack has already been referred to. It now remains to name the treatment of those cases in which the symptoms of irritation or augmented muscular excitability, described in the diagnosis, are not present; generally of long standing. And here, again the treatment will be nearly similar to that named for apoplexy and softening of the brain.

To promote absorption as well as to overcome, if possible, the

degenerate condition of the brain-structure, the Iodide or Bromide of Potassium, or of Ammonium, should be employed, changing them occasionally that the system may not become too much habituated to the influence of any one of them. And to each dose, should the patient be anemic, or present symptoms in which iron would be indicated, five drops of a Solution of the Perchloride, or the soluble Pyrophosphate of Iron may be added. With a view of still farther aiding in removing the lesions, and gently stimulating the coats of the blood-vessels, Tincture of Arnica may be administered internally, either alone or in conjunction with Tincture of St. John's Wort. The following will be found an excellent preparation: Take of the Ethereal Oil of Arnica Flowers four drops, St. John's Wort Flowers one drachm, Spirit of Nitric Ether half a fluidounce; mix, and macerate for seven days. The dose is from five to twelve drops, four times a day. The Rhus Toxicodendron has also proved serviceable in some cases, but great caution is required in its use. A very excellent preparation for long-standing cases, accompanied with much debility is: Take of Xanthoxylum, Iridin, each one drachm, Horseradish two ounces, Mustard one ounce, Sweet Flag one ounce, Whisky four pints; mix, macerate for fourteen days and filter. The dose varies from a fluidrachm to half a fluidounce, alone or in sweetened water, three or four times a day.

Some active stimulating liniment should be applied to the affected muscles for the purpose of exciting them to action; and also to the spinal column to act as a derivative; and the flesh-brush should be used daily. As a liniment to the spinal column, I know of nothing superior to the Compound Tincture of Capsicum, which may be applied over the whole length of this column, by means of a flannel rag—repeating the application daily, or twice a day, as the case may require. As pointed out in the diagnosis, where there is no increased muscular excitability, electrogalvanism may be daily applied to the affected muscles only, in order to arouse them, if possible, into normal activity. Strong counter-irritation to the occiput and nape of the neck, or the Compound Tar Plaster, will frequently prove advantageous in cases where there is no anemia, and no marked debility or great loss of vital power. Nux Vomica or Strychnia, or Brucia, are absolutely inadmissible in this disease, most commonly effecting more injury than benefit. In fact, these agents, as a general rule, should not be used in cases of paralysis in any form, due to cerebral lesion or to irritation or augmentation of the vital properties of the spinal cord.

The bowels, skin, and kidneys must be kept in as normal condition as possible; the bladder be especially attended to, to ascertain that it is properly evacuated from time to time; the powers of the system must be supported by a generous diet, and non-stimulating tonics, as the Elixir of Iron and Cinchona, Phosphorated Oil, Cod Liver Oil, etc.; indeed, in all cases of paralysis, one of the most important points of treatment is, not only to stimulate the affected muscles to action, but also to keep up their nutrition as much as possible. Moderate exercise, and especially of the affected muscles, should be taken daily, active if possible—if not, passive; tight clothing, especially about the neck and superior extremities, must positively be avoided; the head should be kept cool all the time, and be moderately raised during sleep; the mind be kept calm and tranquil, and the sleeping apartments cool and well ventilated. The body of the patient should always be warmly clad, or maintained at a proper temperature both during the day and the night. Cool or warm douches to the head and along the spinal column will sometimes prove advantageous, but general warm or cold baths should be avoided; other means may prove useful as advised under the hygienical measures for Softening of the Brain, and Apoplexy, *which see*.

9. PARAPLEGIA is paralysis of the lower half of the body, which is deprived of motion, of sensation, or of both. It is exceedingly rare that this form of palsy is due to a cerebral lesion, but almost always to a disease of the spinal cord,—with the exception of those cases resulting from poisons or from reflex action, etc. These lesions of the spinal cord are myelitis, softening, or hemorrhage, and which conditions may be *caused* by concussion of the spinal cord; laceration or division of its substance; extravasation of blood; spinal congestion; inflammation; scrofula; tubercles; tumors; as well as the causes named under the head of Chronic Myelitis.

The *symptoms* of paraplegia, the same as with the other forms of paralysis, vary considerably, sometimes the attack coming on suddenly, and at other times gradually, depending, probably, upon the character and severity of the spinal lesion producing it. If this lesion be located in the inferior lumbar portion of the cord, the inferior extremities and muscles of the pelvis will be affected; if it be seated in the dorsal part, or in the entire lumbar region, the sphincters and abdominal muscles will be involved in addition to the above. If the superior part of the cord be affected, the paralysis will extend to the superior extremities, and there will be more or less difficulty in swallowing and in breathing, and the case

generally proves fatal, indeed, almost immediately so, if the lesion exists above the origin of the phrenic nerves. We commonly find the paraplegia to be less marked on one side than on the other; and with the loss of motion that of sensation may also be included, or, according to Brown-Sequard, we may have a loss of motion on the same side as the lesion, when this is confined to a lateral segment of the cord, at any point of it whatever, and, at the same time, a paralysis of sensation only on the other side. In some cases the affected muscles gradually become atrophied; while, in others, nutrition and circulation continue as usual, and the muscles respond to electric excitation. Sometimes the muscles contract, so as gradually to become hard and rigid, producing a greater or less degree of deformity.

Paraplegia from spinal lesion has been divided into two forms, one, arising from congestion, meningitis, myelitis, or hemorrhage in the gray matter of the spinal cord; the other, to white softening, or hemorrhage in the spinal cord. In the first, there is too great an amount of blood passing into the cord; in the latter, there is not enough.

Paraplegia due to *hemorrhage in the gray matter of the spinal cord*, is sudden in its attack, and is attended by pain at that part of the cord where the hemorrhage occurs, by pain after pressing upon the spine, as well as pain in those parts of the body receiving their distribution of nerves from the diseased part of the cord. From the very commencement of the attack the rectal and vesical sphincters are more or less palsied, so that the patient can not retain his urine or his feces. Sometimes, inflammation of the parts of the cord surrounding the clot occurs, with symptoms of myelitis. If the effused blood be small in quantity, the symptoms will not be very severe, and the patient may recover in a few months. But if the quantity effused be large, the fluid will pass downward along the central canal of the cord, and may rupture the gray cornua, more particularly the anterior ones. If the hemorrhage is limited to one lateral half of the gray matter, there will be a paralysis of motion on the side of the hemorrhage, and paralysis of sensation on the opposite side. One of the earliest symptoms of paraplegia from hemorrhage in the gray matter of the cord, is a diminution of sensation, which becomes perfect as soon as the whole of this gray substance is altered by the effused blood.

Hemorrhage between the spinal cord and the bony envelope, the blood being effused either between the pia mater and the arachnoid, or between the dura mater and the vertebræ, is manifested by pain

along the whole length of the cord from the seat of the hemorrhage to the inferior extremity of the vertebral canal. A complete paraplegia comes on immediately, with often, tetanic convulsions; and from its influence upon the circulation or respiration, the attack almost always proves fatal. Fortunately, it is a very rare affection.

In paraplegia, the result of *white or non-inflammatory softening of the cord*, the patient at first complains of weakness, which gradually increases, and is felt more especially at the knee and ankle joints; it becomes difficult for him to raise his leg, as in mounting a pair of stairs, etc.; the gait becomes tottering, or resembling that of an intoxicated person, more especially when he does not direct the motions of the legs with the aid of vision. In the recumbent position, he can move his legs, though feebly, provided he sees them. The paralysis progresses, motion, and finally sensation, become more or less diminished; voluntary power over the bladder and rectum is lost to a greater or less degree; no pain is complained of, or but very slight pain, in the spinal column or in the palsied parts; the urine is seldom changed; and the temperature of the limbs is often above the normal standard.

In the *diagnosis* of paraplegia, great care is required to discriminate, as much as possible, between the several kinds, in order to avoid an erroneous and injurious treatment. Some assistance may be derived from the remarks heretofore given concerning the symptoms and diagnosis of chronic meningitis, chronic myelitis, and reflex paraplegia, in connection with those that follow.

The symptoms of irritation, as convulsions, cramp, twitchings, erection of the penis, formication, and itching; diminution of temperature, wasting of muscles, œdema, bed-sores, and alkaline urine, are those accompanying paraplegia from inflammation, congestion, or irritation of the spinal cord, with increased amount of blood in it. In those cases where these symptoms are absent, the paraplegia is due to reflex action, or to *white or non-inflammatory softening of the cord*, in which there is an insufficiency of nutrition, and, in most cases, an insufficient amount of blood in the cord. (*Brown-Sequard.*)

When the paraplegia attacks suddenly, it is due to hemorrhage in the spinal cord (gray matter) when convulsions are absent, when there is a more marked anæsthesia, and when the pain is confined to that part of the spinal cord where the hemorrhage occurs. It is due to hemorrhage outside of the cord, in the vertebral canal, when tetanic convulsions are present, when the anæsthesia is less marked, and when the pain is of considerable extent along the

spinal column. Paraplegia from white softening comes on gradually; but should its attack be sudden, it may be discriminated from the preceding, by the entire absence of pain in the spinal column, and by the absence of the above-named symptoms of irritation. Sometimes softening and hemorrhage may exist together, the same as in the brain.

The following diagnostic remarks are borrowed from Brown-Sequard:

Urinary Paraplegia is preceded by an affection of the bladder, the kidneys, or the prostate; the lower limbs only are generally palsied; there is no gradual extension of the palsy upward; the paralysis is usually incomplete, some muscles being more affected than others; reflex power is not much augmented, nor wholly lost; the bladder and rectum are very slightly, if at all, paralyzed; spasms are rarely observed in the affected muscles; pains in the spine, spontaneous, or caused by pressure, application of warm water, hot sponge, ice, etc., are very rare; no sense of pain or constriction around the chest, or the abdomen; there is no formication, no pricking, no disagreeable sensation of heat or cold; anæsthesia is rare; obstinate gastric derangement is usually present; changes in the disease of the urinary organs effect corresponding changes in the degree of the paralysis; cures are frequently and rapidly obtained, and, sometimes spontaneously, following amelioration or cure of the urinary lesion.

Paraplegia from myelitis has no urinary disease except that resulting from the paralysis; the urine is almost always alkaline, while in cases of reflex paraplegia not due to lesion of the urinary organs, it is ordinarily acid, the same as in health; other parts are generally paralyzed besides the lower limbs; the palsy gradually advances upward, and is very often complete; the degree of paralysis in the various muscles of the inferior extremities is about equal; reflex power may be lost, or, in some cases, increased; complete paralysis, or nearly so, of the bladder and rectum; spasms or twitchings always present; more or less pain is always present, either spontaneous, or produced by external excitations; a sense of constriction, as if a cord were tightly bound around the body at the upper limit of the paralysis; formications, prickings, and sensations of heat and cold, are more or less constantly present; anæsthesia is often present, and, always, numbness; if the myelitis is not in the upper part of the cord, gastric digestion is good; ameliorations are extremely rare, and do not follow changes in the urinary lesions; a complete cure is seldom attained; frequently

the progress toward a fatal termination continues slowly and gradually.

Paraplegia due to *spinal meningitis* is attended by spontaneous acute pains, radiating from the spine to the lower extremities; cramps; pains when the inferior extremities or spinal column are moved, and rigid spasm of the muscles of the back. Paraplegia from a *diseased bone, tumor, or fibro-cartilage* pressing upon the cord, is accompanied with a pain somewhat resembling that of neuralgia, a sense of tightness, and some formication, which are confined to those parts of the body receiving their nerves from that portion of the cord pressed upon, unless there be a meningitis or myelitis, when these same symptoms may be present in any part of the body below the seat of the pressure, at which point there will be pain or tenderness. Paraplegia, due to a *tumor in the gray substance of the cord*, is attended at the commencement with loss of sensation which may be more marked than that of motion; reflex power becomes greatly increased in parts of the cord below the tumor, so that the slightest excitations will give rise to violent reflex movements. Paraplegia due to *hemorrhage in the spinal canal*, is preceded for some time by a vague pain along the spine; the paralysis occurs suddenly; convulsions or spasmodic twitchings are frequent, and sensibility is much diminished, when the blood is effused into the gray substance. In paraplegia due to *congestion of the cord and its membranes*, the paralysis is greater after a night's rest, or when the patient has been sitting for a length of time. In paraplegia due to *non-inflammatory softening of the cord*, there is no outside irritation as in reflex paraplegia; the paralysis comes on more or less gradually, and sometimes a chalky deposit in some of the superficial blood-vessels of the head or limbs may be observed, or the arcus senilis. Paraplegia due to an *obstruction in the aortal circulation*, or in its principal ramifications in the pelvis, is attended with alternations of nutrition and pains in the palsied muscles; by an increase of the paralysis on making much exertion of the inferior extremities, and by the diminution of the paralysis after some rest. Paraplegia due to *compression of the pelvic nerves* is attended with severe pains in the pelvis, as well as severe cramps in the legs. Paraplegia due to *atrophy of the cord*, is apt to be preceded by tremulousness, unsteadiness in walking, difficult urination, spasmodic contractions, or sudden jerkings of the muscles. Paraplegia, the consequence of *injuries, of poisons, hemorrhages, concussion*, or, occurring as the result of *exposure to wet and cold*, as frequently met with among soldiers whose camps or

tents are in damp grounds, may readily be determined by the history of the case.

Dr. Wm. Gull states that from *post-mortem* investigations made by himself, the spinal cord may have its functions not only impaired, but even suddenly lost, as far as motion is concerned, without any great anatomical lesion being present. Among a number of paralytic cases he gives the following results of *post-mortem* examinations of some of them:—In one case, the most marked symptom was a complete inability to control the muscular contraction, with numbness and formication of the hands and feet; the autopsy revealed atrophy of the whole length of the posterior columns. Brown-Sequard found a diminution of sensation when the whole length of these columns was destroyed; and exalted sensation below the seat of the lesion when their destruction was of limited extent. In another case, attended with numbness and debility of the limbs for a number of months, sensibility being unimpaired, Dr. Gull found atrophy of the gray matter of the cord, and chronic inflammatory degeneration of the posterior columns. A third case, attended with paralytic debility of the legs, an inability to regulate the muscular contractions, with atrophy of the voluntary muscles, gave, at the autopsy, a chronic inflammatory degeneration of the posterior columns. In another case, in which the attack commenced with acute symptoms, the arms being debilitated, the legs almost completely paralytic; with paralysis of both seventh nerves, the cervical and dorsal portions of the cord were found to be somewhat softer than natural, and after hardening and making sections of the cord, recent exudation cells were observed, disseminated interstitially among the tissue in the anterior part of the commissure, throughout the length of the cord, chiefly in the lumbar and superior cervical portions, and, principally, in the upper part of the medulla oblongata. A fifth case was one of complete paralysis from powerful efforts to lift a heavy weight, the only morbid changes observed, was a softening of the cord opposite to the fifth and sixth dorsal vertebrae, all the columns presenting a thick mucopuriform fluid, of a greenish color, slightly tinged with brown, and which consisted of dissociated nerve-substance and a few granules.—The next case was due to injury of the posterior cervical portion of the spinal column, in which there was paralysis of the left arm, the legs, and the sphincters, with loss of sensibility, followed in a few hours by exalted sensibility; the substance of the cord in the region of the fourth and fifth cervical was found in a contused state, there being an ecchymosed condition of the posterior horn of gray matter on the left side, as well as of the adjacent part of the

lateral and posterior columns; slight ecchymosis was also noticed on the right side, in the posterior column, and in the anterior cornua of the gray matter. A seventh case was paralysis of both the upper and lower extremities, with loss of sensibility in the palsied parts, the result of a fall backward from no great height; with these symptoms there appeared to be a paralysis of the intercostal muscles, and the skin became intensely hot; an effusion of blood was found external to the theca vertebralis in the neck, which came from a fracture of the lower part of the body of the fourth vertebrae, and the intervertebral substance was torn; no injury to the cord. (*Guy's Hospital Reports*, 3d Series, Vol. IV, 1858.)

The *prognosis* of paraplegia from hemorrhage in the gray matter of the spinal cord is very unfavorable, usually proving fatal in a few weeks, and occasionally in several months or even years; in some rare cases a degree of amelioration may be effected. These results, however, depend upon the character of the lesion, its location, and extent. A hemorrhage is always more serious than softening, not only because of the liability to a renewal of it, but also because of the morbid changes effected by the effused fluid in the substance of the cord. Paraplegia due to hemorrhage in the vertebral canal is rapidly fatal. When white or non-inflammatory softening occasions the palsy, a cure is seldom, if ever, effected, though, from an arrest of the spinal lesion, the paralysis may become much improved; if the softening be confined to the inferior dorsal portion of the cord, the patient may live for many years. Paraplegia may prove fatal by passing into a general palsy, or, by morbid changes effected in the urinary organs, by sloughing bed sores, exhaustion, epilepsy, or convulsions.

The *pathological appearances* will resemble, according to the cause of the paralysis, those of chronic myelitis, or of chronic meningitis. Softening of the cord, ecchymosed spots, engorgement of blood-vessels, vascularity of the membranes, atrophy and flaccidity of the spinal marrow, hemorrhage into its substance, or in the vertebral canal, and such other changes as named above in Dr. Gull's cases. Under the microscope the softened parts of the cord are found to consist of fragments of nerve tubes, globules with double outlines, granule cells, granules, fatty molecules, and, perhaps, blood corpuscles.

The *treatment* for paraplegia from white or non-inflammatory softening will be similar to that already named for chronic myelitis, reflex paralysis, or for hemiplegia due to non-inflammatory softening of the brain, viz.: Iodide of Potassium or of Ammonium, in doses of from three to five grains three times a day, in order to produce

absorption of effused fluids, and which should be taken about an hour before each meal to avoid disengagement of the Iodine from the action of the gastric juice. In conjunction with this, tonics should be used, as the Elixir of Cinchona and Iron, or a combination of Sulphate of Quinia, Prussiate of Iron, and Alcoholic Extract of Black Cohosh; it is better not to employ Strychnia, unless the paralysis be very slight. The cold douche to the spine, or the shower bath will also prove serviceable, improving the nutrition of the cord. Sea-bathing is also useful. The limbs should be frequently shampooed, and electro-magnetism be applied to the paralyzed limbs. Stimulating liniments and frictions may also be applied along the spinal column, for the purpose of inviting a gentle determination of blood to the part. The diet should be nutritious and easy of digestion; the bowels and bladder be kept regular; and at night, the patient should lie as much as possible upon his back. Sulphur, Carbonate of Ammonia, Cod Liver Oil, Rhus Toxicodendron, and Bryony, have been occasionally used with success in this affection. Phosphorus, three or four grains dissolved in Olive Oil, and given in doses of three drops a day, gradually increased to ten, provided it does not occasion nausea or vomiting, is occasionally beneficial. And the Iodate of Strychnia, in doses of one-eighth of a grain twice a day, carefully and gradually increasing the dose, has also proved of service.

In hemorrhage of the vertebral canal, the paraplegia proves fatal, and there is no successful treatment known.

In paraplegia from hemorrhage into the gray substance of the cord, or, attended with symptoms of irritation, there will be a slight variation in the treatment, from that pursued for cases of white softening. Iodide or Bromide of Potassium may be given in doses of five or six grains, repeated three times daily. A pill composed of Sulphate of Quinia, Prussiate of Iron, Extract of Belladonna, and Alcoholic Extract of Black Cohosh will be found very useful. Or, a pill may be composed of powdered Ergot, Extract of Belladonna, and Alcoholic Extract of Black Cohosh. The preparation of Arnica Flowers, named under Hemiplegia, on page 244, will frequently prove advantageous. The system should be supported by tonics and proper nourishment. In these cases of congestion or irritation of the cord, great advantage will be derived from the local application of the Compound Tar Plaster over the diseased part of the spine; or, in some cases, dry cupping, or firing along the whole course of the spinal column, from the commencement of the diseased region downward; and in very severe cases, the hot douche, setons, issues, or even moxæ or the actual cantery; of course, some

discrimination is required in the selection of cases in which any one of these may be used. As a general thing, the Compound Tar Plaster will be suitable in by far the greater number of cases; but its application should always be omitted when too much depression or exhaustion follows its employment.

The bowels and urinary organs should be kept regular; the skin should be attended to; the diet should be nutritious but light; the patient should at no time lie upon his back; and electro-magnetism should be applied to the paralyzed muscles only after the symptoms of irritation have passed away. It is a mistaken idea that electricity passed through a softened brain or spinal cord will aid in curing it; as far as my own observation goes, it only appears to aid in hastening the extension of the lesion. It will be useful, however, when applied to the paralyzed muscles themselves, or to hypertrophy, indurations, tumors, etc., of the brain or cord, not connected with softening or effusion of blood.

For the sloughing ulcers which are so often present with paralytic patients, the following preparation may be applied: Take of powdered Camphor half a drachm, Sulphate of Zinc half a drachm, Strychnia one grain, Glycerine Ointment one ounce; incorporate the articles thoroughly. This may be applied upon the part by means of lint, upon which a small portion has been spread. Electro-magnetism should also be applied upon and around the ulcerated part. Injury to the spinal cord is usually followed by these sloughs, for which Brown-Sequard recommends the application of morsels of ice to the parts threatened or affected, repeating it from six to ten times a day, so as to cause contraction in the blood-vessels of the parts, each time; then, removing the ice, and immediately applying a poultice or compress as hot as can be borne without injuring the tissues. By these alternations of contraction and relaxation, a change in the circulation and in the nutrition of the parts is produced.

10. GENERAL PARALYSIS is the term applied to that form of palsy which attacks both sides of the body; the patient's movements are more or less interfered with, speech is indistinct, the countenance assumes a peculiar inexpressive appearance, and the mental faculties become more or less gradually perverted with hallucinations. There appears to be a want of command over the co-ordinate action of the limbs, and the walking is of a peculiar character, a swaying from one side to the other. The muscular paralysis extends and becomes more severe until the patient can neither move, nor speak so as to be understood. Sometimes there is a lesion of the intellect from the commencement, or, at least, the

friends do not recognize the disease until symptoms of dementia are observed. Loss of memory is, however, a very early symptom, and may continue for some time before the manifestation of dementia; and, sometimes, the insanity will be the first recognized symptom of the disease.

General paralysis may commence as a hemiplegia, as a paraplegia, or, it may commence in the feet and lower legs, and gradually extend upward. The part first attacked is always more intensely paralyzed than parts subsequently affected, continuing so throughout the whole course of the disease.

Emaciation, marasmus, and gangrenous ulcerations occur at a later period of the disease. Impotency is one of the earliest symptoms. The appetite is usually good, sometimes voracious; pulse generally accelerated; pupils contracted, or unequal, occasionally natural; general sensibility impaired, or obtuse.

In some cases several years may elapse before the fatal period arrives; in others it may occur within a few weeks or months. Coma, convulsions, obstinate diarrhea, painful muscular contractions, or, some lung difficulty, frequently precedes death.

The disease may be *caused* by falls upon the head, masturbation, inordinate venery, intemperance, excessive irritation, or excitement of mind, etc.

In the *diagnosis* of general paralysis, it may be determined from Duchenne's "*ataxie locomotrice progressive*," by the tremors, difficulty in articulation, loss of memory, in the early stage, and the dementia in the latter stage; in *ataxie locomotrice* there is apt to be strabismus, amaurosis, sharp, characteristic pains, but the speech and intellect remain unimpaired.

It may be determined from general paralysis, the result of a spinal lesion (*tabes dorsalis*), by the following symptoms: In *tabes dorsalis* the disease commences with a numbness of the feet, sensation remaining normal, gradual feebleness of the muscles of the lower limbs, frequently a disturbance of vision, no impairment of intellect, more or less palsy of the bladder and intestines, great distress in the gastric region, sharp, shooting pains in the inferior limbs, atrophy and feebleness of the muscles, especially those of the back, legs, and nates, and their non-tractility under electro-magnetic influence. In general paralysis there is no gastric difficulty, no severe pains in the limbs, and no atrophy of the muscles, and the intellect is always more or less impaired.

The *prognosis* is unfavorable; recoveries seldom occur.

The *pathological appearances* vary; usually the dura mater ad-

heres to the skull, and to the subjacent membranes, at various places, by strong bridges; the pia mater may be much injected, and adhering to the neighboring tissues; there may also be adhesions of various parts of the brain by small filamentous cords; injection of blood-vessels of the brain, at one or several parts; arachnoid thickened, milky, opaque, or translucent; softening of various parts, or a general softening of the brain-substance; effusion of serum in the ventricles, or at the base of the brain, etc.; together with various other results of congestion or degeneration of the brain.

The pathological appearances in general paralysis from *tabes dorsalis* will depend entirely upon the nature of the change undergone by the spinal cord, as, softening, induration, atrophy, effusion of fluid between the membranes, injection of the venous sinuses, etc.

In the *treatment* of this disease, the same measures should be adopted as are advised for Hyperemia of the Brain, Softening of the Brain, Hemiplegia, and Apoplexy—according to the combination of symptoms, circumstances, and effects of the medication, remembering that tonics and nutritives form a very important part. Never having treated a case of this disease, I can say nothing from actual experience.

Tabes dorsalis is more commonly the result of excessive masturbation, or venery. The body is bent over from debility of the spinal column; the lumbar region is either straight or convex; the gait is unsteady, vacillating, like that of an intoxicated person; the knees bend under the weight of the body; the eyes are sunken; the face pale; the whole body emaciated; the genitals flaccid, soft, and wasted, together with hypochondria, mental depression, leucorrhea and hysteria in females, perhaps epilepsy, insanity, and the various strange symptoms frequently observed among masturbators. Ataxic musculaire locomotrice has also been termed *tabes dorsalis*, but it is not exactly the same disease as the one referred to at this place.

The *treatment* of *tabes dorsalis* consists, first, in an absolute and permanent relinquishment of the cause; and then, internal measures to overcome any spinal lesion, as, Iodide of Iron, Iodide of Ammonium, etc.; together with ferruginous or vegetable bitter tonics; cold or warm douches to spinal column, with frictions and stimulating liniments; nutritious diet; well-regulated exercise in the open air; and the usual therapeutical and hygienical measures advised for Impotency and Spermatorrhœa. The disease, however, is not always curable, though much may be done to remove unpleasant symptoms, and prolong the patient's life. It is very

difficult to detect the peculiar character of the lesion which the spinal cord has undergone in this affection.

EPILEPSY.

Epilepsy or Falling Sickness is not a disease of itself, but is only the symptom of disease, or of certain obscure abnormal conditions of the nervous centers, being manifested by recurring attacks of a sudden deprivation of the senses, or insensibility, with or without spasmodic contraction of the voluntary muscles, quickly followed by more or less violent convulsive distortions, and, as the attack declines, the patient passes into a state of sopor which continues for an hour or two, or longer. All persons are liable to it, but it more commonly attacks the young, and those in early adult life; according to Sieveking, Andral, Esquirol, and other writers, females are more subject to it than males, especially after the tenth or twelfth year, though this is not in accordance with my own observations, in which male epileptics have a decided preponderance. The disease may commence at any period of life, but more commonly during infancy and childhood.

The *causes* of epilepsy are involved in great obscurity, notwithstanding the efforts made by physiologists to unravel them. The epilepsy is generally supposed to originate in some lesion of the brain, or of the spinal cord, and is then termed, idiopathic, centric, or intrinsic; or, from reflex action, and is then termed, secondary, excentric, or extrinsic. The morbid conditions which may give rise to the idiopathic form, are, lesions of the nervous centers, as, a cerebral or spinal tumor, chronic inflammation of the brain, ramollissement of the brain, or some other cerebral or cerebro-spinal disease.

Idiopathic epilepsy may be hereditary, and is apt to occur in the offspring of those who have weakened their nervous centers, and, perhaps, produced disease therein, by masturbation, excessive venery, or intoxication; it may also attack those whose parents were subject to apoplexy, paralysis, cerebro-spinal disease, or to sudden and violent fits of passion; indeed, it may be said that the offspring of those who have thus labored under nervous affections, receive that peculiar organization from their progenitors, which predisposes them to epilepsy and allied affections. Again, the disease of the brain occasioning the epileptic attacks may be the result of premature synostosis of the cranial sutures and fontanelles; masturbation; metastasis of gout or rheumatism to the brain; repeating hemorrhages; morbid state of the blood; inju-

ries to the cranium producing compression; continuous-pressure upon the nerve-substance by osseous spicula; anemia, or want of nutrition; hyper-nutrition, etc. Masturbation is a most prolific source of this disease; among sixty-five patients, I ascertained that masturbation had been carried to a great extent in twenty-six, and moderately in sixteen.

The secondary form of epilepsy may arise from numerous causes, as, gastro-intestinal derangement, acid stomach, worms, improper food, etc.; painful dentition; blows; wounds; external violence to the head or spinal column; uterine irritation; calculi in the bladder or kidneys; gall-stones in the excretory duct of the liver; suppression of habitual or customary discharges; violent mental emotions, as, anger, fear, terror, distress, etc., intoxication; profuse hemorrhages; acute pains; repercussed eruptions; overpowering or peculiar odors; tickling the soles of the feet, or the sides; great fatigue; long protracted watching, etc.

Of course, it is not only difficult, but almost impossible to determine the true cause of any given epileptic seizure, though the exciting cause may frequently be ascertained by a careful study of the case.

In order to show the unsettled state of the etiology of idiopathic epilepsy, I will briefly refer to the views of several eminent physiologists. Dr. Prout maintained that persons whose urine contains an abnormal quantity of soda or potash, were especially liable to spasmodic diseases. Dr. Robert Hunt contends that an abnormal excess of alkali in the blood directly predisposes the nervous system to disease, and not only this, but, also, that it probably causes various chemical changes in the blood, which result in the generation or retention of noxious matters in the system, which excite a tendency to spasm and convulsions. From the uniform deficiency of organic principles in the urine, as urea, and the excess of mineral matters, especially chloride of sodium, he infers that they must have some connection with the state of the blood and the disease in question, as cause and effect. Dr. Robert Todd holds that the "peculiar features of an epileptic seizure are due to the gradual accumulation of a morbid material in the blood, until it reaches such an amount that it operates upon the brain, in, as it were, an explosive manner; in other words, the influence of this morbid matter, when in sufficient quantity, excites a polarized state of the brain, or of certain parts of it, and these discharge their nervous power upon other parts of the cerebro-spinal center in such a way as to give rise to the phenomena of the fit." Understand this whoever can. Dr. Marshal Hall considers that

no lesion of the cerebral system, limited to the cerebrum, *can* be attended by spasm or convulsion; while, on the other hand, no structural lesion, short of destruction, *can* occur *without* exciting spasm or convulsion. Disease of the cerebral center, may, by downward pressure, affect the spinal center. The convulsion is produced by this pressure or irritation upon this center; the cerebral anæsthesia, by spasmodic action of the muscles of the neck, (*trachelismus*) which, pressing upon the jugular and other veins of the neck, causes extra-cranial and intra-cranial venous congestion and its consequences. Dr. Sieveking, considers hereditary influence as a predisposing cause of epilepsy; he also believes that a derangement in the quantity or quality of the blood circulating in the brain, may produce an irritation giving rise to epilepsy, and which symptom is subsequently repeated from time to time by habit, and a peculiar susceptibility which renders the individual more liable to repetitions of the attack. He believes epilepsy to be an affection of the brain, particularly of the sensory ganglia, the spinal cord being involved secondarily. The immediate cause of the epileptic attack, is, in his opinion, an increased flow of blood upon the brain, though a general state of anemia may be present in most cases. Dr. Reynolds takes the ground that the immediate cause of convulsions generally, is the same in all cases, and consists in an unhealthy augmentation in the nutritive function of the nervous centers, and that the primary causes are those which give rise to this morbid augmentation. Hereditary tendency, as well as the commencing period of puberty, are very common predisposing causes to epilepsy. He says: "There appears no reason for doubting that the immediate cause of loss of consciousness is arrest of the cerebral circulation, owing to the contraction of the vessels, through irritation propagated along the vasomotor nerves from the medulla oblongata; and thus the latter is shown to be the organ wherein both elements of the epileptic paroxysm (convulsions and unconsciousness) have their origin." The nature of the morbid changes which occasion the attack in the first instance is thus stated by him: "Nutrition is affected dynamically and temporarily; there is no recognizable departure from textural integrity; there is merely the difference that exists in health and in all organs between action, over-action, and repose; after a time, and by frequent repetition of attacks, the changes induced temporarily, become permanent, and the texture, which is the product of foregone nutrition processes, is altered statically and persistently." These changes consist in increased action; we observe in the epileptic seizure evidence "not only of disturbed equilibrium, but of dis-

torted, misdirected, and exaggerated power.”—Dr. Radcliffe considers all convulsive diseases to be due to deficient or disturbed innervation; and the predisposition to them may be caused by anything which prevents perfect hematosiis, thereby impairing the normal activity of the nervous centers, either by lessening the power of their arterial circulation, or by producing an organic lesion in them. He does not think that the facts advanced by him would hardly warrant the idea that epilepsy is connected with anything like overaction of the nervous system. He also advances a hypothesis of muscular action, which is that *muscular contraction* is not due to the excitation or stimulation of any muscular contractile property, but is merely the natural result of the cessation of muscular elongation; and that *muscular elongation*, or relaxation, is occasioned by an active condition of the muscles, produced by nervous influence, galvanism, irritation, etc., and according to which hypothesis he considers the epileptic convulsions to be due to a deficient or deranged supply of nervous influence to the muscles convulsed, this cause being the result of a similar deficiency, etc., in the functions of the nervous centers. He considers the convulsions, therefore, due to a lack of circulatory energy, which occasions deficient nervous activity, and the state of unconsciousness to an inactive or comatose condition of the brain. He says: “From these previous investigations,” (concerning the physiology of muscular action), “it was to be expected that coma and convulsions might go hand in hand together; for muscular contraction, according to these investigations, is to be looked for when a failure in the action of the nervous centers causes a failure in the amount of nervous influence distributed to the muscles.”—Trousseau is disposed to attribute epilepsy to a diathetic state, which keeps the patient in such a condition that, with or without an occasional cause, he may be seized with a fit of epilepsy. A man may be termed epileptic even when the attacks are absent. “But it is always the diathetic condition that determines the form of the accidents. Thus, supposing two patients suffer from a syphilitic or tubercular cerebral affection, if one of these possesses the epileptic diathesis, the symptoms will be those of epilepsy, while the other will exhibit the ordinary symptoms of the cerebral affection.”—Brown-Sequard, from the results of certain interesting experiments instituted by himself upon animals, is rather disposed to connect them with the etiology of epilepsy in man. Epilepsy is mostly generated by disease of the spinal cord. He says: “It can not be doubted that a disease of the spinal cord or of its membranes, as well as an affection of any centripetal nerve in the human body, may be the primitive origin of a real epilepsy quite similar to the

erroneously-called idiopathic epilepsy." Again, "in most cases of genuine and complete epilepsy, as well as in cases of simple vertigo, there is an irritation starting from some point of a centripetal nerve, especially from its peripheric parts in the skin or in the various mucous membranes;" "but almost all the recent writers on epilepsy having considered those cases as quite special, I must insist on saying, that even in the so-called idiopathic epilepsy there may be found an irritation starting from some centripetal nerve and generating the convulsion; and I must add also, that there is no radical difference between the symptoms of the sympathetic epilepsy and those of the pretended idiopathic." He likewise remarks: "Epilepsy seems to consist essentially in an increased reflex excitability of certain parts of the cerebro-spinal axis, and in a loss of the control that, in normal conditions, the will possesses over the reflex faculty. The base of the encephalon, and especially the medulla oblongata, is the most frequent seat of the increase in the reflex excitability, so that this part of the nervous center is the ordinary seat of epilepsy. The disturbance in the functions of the cerebral lobes during and immediately after a fit, and in the inter-paroxysmal periods, is chiefly due to the alteration taking place in the brain during the fit. . . . The same cause that produces the first convulsions, produces also a contraction of the blood-vessels of the brain proper, and which contraction is necessarily followed by the loss of consciousness."

These are briefly the views of some of our most eminent physiologists relative to the cause of epilepsy, and they are truly discordant, limited, and unsatisfactory; and, in our present imperfect knowledge of the etiology of this affection, we may probably give an equally satisfactory explanation, in the following general proposition, viz.; all convulsive affections, from the simplest agitation of a single muscle to the most violent convulsive paroxysms of all the voluntary muscles, are due to a peculiar morbid condition of the nervous centers, which predisposes to abnormal action of the nervous system, or to convulsive phenomena, when these centers are excited by certain irritations; the peculiar character of the convulsive phenomena depending upon the particular part or parts of the nervous centers that are morbidly affected, the degree and extent of the morbid condition, and also upon the location and degree of the abnormal irritation which acts as an exciting cause. Also, the morbid condition which gives rise to the predisposition to convulsive attacks, may be inherited from progenitors themselves similarly predisposed, or, whose nervous systems have been impaired by excesses or other influences; or it may be acquired by certain agen-

cies that will develop morbid nervous susceptibility, or even actual lesion of the nervous centers, as, by masturbation, venereal excesses, frequent intoxication, etc.

The *symptoms* of epilepsy vary with many persons; though, in a complete attack, the predominant symptoms are about the same. Persons apparently in good health may be attacked suddenly, without any premonitions; though many patients have clear intimations of the approaching convulsions, which may occur within a few seconds of the attack, and, in some cases, which manifest themselves for several days previous to it. Thus, there may be unpleasant and disturbed dreams; or spectral illusions; or a peculiar operation of the mind, incongruous ideas, great irritability of temper, or a remarkable intellectual activity, etc. The more common premonitory symptoms are, a heavy pain in the head, dazzling of the eyes, dimness of vision, tinnitus aurium, slight flushing of the face, dilatation of the pupils, palpitation of the heart, flatulency, weariness, coldness of the limbs, or chills and shiverings, one or more of which may precede the convulsive attack. Frequently, a peculiar sensation, it may be of cold, pain, heat, itching, or like the crawling of an insect, is developed suddenly in a toe, a limb, in the abdomen, or in the back, and passes gradually toward the head; as soon as it reaches the head, the epileptic seizure comes on, and the patient falls as if struck. This sensation is called the *aura epileptica*. Dr. Sieveking states that it appears to him that the patients become insensible when the aura has arrived at the throat. In some cases, the patient imagines he sees a specter coming toward him, and falls into a paroxysm as soon as this figure comes in contact with him. Sometimes very strange and unaccountable phenomena of some one or more of the senses precede the convulsive fit.

But whether there be premonitory symptoms or not, the patient, when attacked, either falls or is thrown to the ground with convulsions, and a deprivation of consciousness and voluntary motion. There is generally a short, piercing shriek, or a strange sound somewhat resembling the barking of a dog, or as if there were a painful, spasmodic gargling of the throat, accompanying the commencement of the attack, followed by the most fearful convulsive struggles. I have observed several patients who, while uttering this noise, were repeatedly turned round in a circle, falling to the ground upon the cessation of the noise. The convulsions are frequently so terrific in appearance, as even for a time to disturb the calmness and presence of mind of the physician; and, it has been the case, that persons, who never before had a paroxysm, have fallen into one upon witnessing a severe epileptic seizure. During the paroxysm the

head is violently rotated, or jerked in every direction; the face is thrown into very distressing and alarming contortions, while the blood-vessels of the head and neck become much swollen; the eyes are fixed and staring, or are convulsively rolled about, or turned out of their axis, so that the conjunctiva only can be seen; while the eyelids remain shut, half closed, or open and close very rapidly; and the pupils are generally contracted, sometimes dilated, and insensible to the action of light. The face becomes injected and livid; the muscles of the jaws contract and relax alternately, sometimes so forcibly as to break the teeth; the teeth gnash together; and the tongue, being forcibly thrust forward, is more or less severely bitten; deglutition being impossible, the saliva is forced out of the mouth in a foam; the muscles of the limbs are violently convulsed, and the limbs jerked in various directions; the breathing is unequal and difficult; the pulse usually small and contracted; the heart beating tumultuously; the urine and feces frequently voided involuntarily; and the sense of feeling entirely lost. Sometimes priapism, attended with a seminal or prostatic discharge, occurs.

After a time, varying from a few minutes to half an hour, or longer, the convulsion ceases, and the patient passes into an apparent deep sleep, from which he gradually recovers, having no distinct recollection of what has transpired from the commencement of the paroxysm. He remains more or less exhausted and sore, requiring one or more days for a restoration to usual health; sometimes headache, a sense of oppression in the head, or stupor, will remain for a time; and, occasionally, apoplexy, followed by death will be the result. At times, the rallying efforts being imperfect, paroxysm after paroxysm occurs, without any waking period or recovery from the convulsions for a long time; or the occurrence of death may precede any rallying attempts. Again, instead of sleep, the convulsions may be followed by more or less active delirium—or, after a long sleep, the delirium may come on and continue for several hours.

With others the attack is imperfect or abortive, constituting the *petit mal* of French writers; the patient may remain with his eyes fixed and open, pupils dilated, motionless, and, for a minute or two, be entirely deprived of consciousness, but without falling; or there may be a waving sensation of the head, a sense of oppression at the heart, with a feeling of intense alarm, which is strongly depicted on the countenance, consciousness, however, remaining, and the business engaged in at the time not being materially interfered with. These mild attacks may occur from time to time, gradually increasing in severity until the genuine epileptic convulsion is established.

In one patient, whom I successfully treated, the only symptom noticed was a sudden cessation of motion, the eyes staring, and the pupils largely dilated, but no loss of consciousness, and while in this condition, which seldom lasted over a minute, he complained of seeing an exact vertical half of a specter, or, as he said, "of a man dressed in white."

The epileptic paroxysm may occur at any time, but it more commonly manifests itself during the night, and these nocturnal seizures may exist for months, or even years, without attracting observation, until the general health as well as the mental faculties have become more or less seriously impaired. Patients suffering from these night attacks labor under more or less debility of the vital, nervous, and muscular systems, have headache, especially on first waking in the morning, and sometimes will notice a laceration of the tongue, and that the urine has been unconsciously voided in the bed; their spirits are depressed, their sleep is not refreshing, they become indifferent to all the important concerns and business of life, and temporary delirium is by no means unfrequent.

Epilepsy sometimes occurs periodically, depending upon its exciting cause; but, more frequently its attacks are very irregular. A paroxysm may occur, and not be followed by another for months, or even years; at other times, it will occur regularly once in every month; and again, it may take place daily, one or more fits occurring every twenty-four hours. When the attacks are of frequent occurrence, the constitution becomes impaired, the mental powers decay, and sooner or later apoplexy, paralysis, mania, or idiotey are the consequences.

Dr. Radcliffe remarks: "As time goes on, the mental faculties recover more and more imperfectly, and more and more tardily, and at last their habitual state may be one of pitiful fatuity, from which no single ray of the divine principle beams forth. Or the moodiness and irritability which follow the attack may become more and more marked, until at last they merge into attacks of downright mania. Or symptoms of paralysis make their appearance; or death may happen in a fit, or shortly afterward. The natural tendency of epilepsy is assuredly toward dementia; and dementia is the final doom of the epileptic, if his disorder be unchecked, and life be prolonged sufficiently; and this equally, whether symptoms of insanity have or have not been developed; but, at the same time, it is possible for an epileptic to have many fits and live many years, without ever losing the powers which are necessary to render him an agreeable and serviceable member of society. If death happens, it hap-

pens most generally from exhaustion in the period of prostration immediately following the paroxysm."

The patient, during the intervals between the fits will present symptoms demonstrating a morbid state of health; he will be more or less irritable; the eyes will be restless and the pupils dilated; there will be more or less difficulty in collecting the thoughts, and a slowness of comprehension; more or less headache, with or without vertigo; constipation; flatulency; eructations; in some cases, a temporary delirium; an inattention to surrounding circumstances, etc.

The *diagnosis* of epilepsy is generally very easy; though it is not always easy to determine its exciting cause. Convulsions alone do not constitute epilepsy, unless attended with a loss of consciousness, indicative of some morbid cerebral condition, and which is the principal feature of the affection. The pupils are insensible to the influence of light or darkness, which is not the case with feigned epilepsy. Hysteria and apoplexy are the affections for which it is more apt to be mistaken. It may be distinguished from *hysteria* by consciousness not being fully suspended; by the foaming at the mouth, the gnashing of the teeth, the biting of the tongue, the hissing respiration, the livid appearance of the face, the distortion of countenance, etc., which are common to epilepsy, and by the absence of those symptoms common to hysteria, as, the globus hystericus, the involuntary fits of weeping and laughing, the absence of distortion of the features; the flushed face; the fixed state of the eyeballs, and, when the hysterical convulsions are severe, the presence of opisthotonos. It may be distinguished from *apoplexy* by this being more usually met with during middle age, while epilepsy is more common at a much earlier period of life, except where the patient is subject to its attacks; in apoplexy, the respiration is stertorous, the muscles are flaccid and powerless, or, if any convulsive action is manifested at the commencement, it is slight and is not repeated, and the pulse is slow and laborious; in epilepsy, respiration is hissing, the muscles are violently and continually convulsed, and the pulse is usually small and contracted.

Epilepsy may be feigned by impostors in nearly every manifestation, except one, and that is, they can not overcome the sensibility of the iris; hence, a strong light held before the eyes will cause pupillary contraction, and when the light is removed, dilatation ensues. In genuine epilepsy the iris is wholly insensible.

It is very important, on account of the treatment, to determine whether the epilepsy is due to some chronic cerebral affection, or to some external cause, and which will frequently prove a difficult mat-

ter. If the seizure be due to an outside exciting cause, and this be removed before the epilepsy effects any cerebral organic lesion, the convulsions cease. An attentive observation of the symptoms during the inter-paroxysmal condition of the patient, will enable the practitioner to determine, in most cases, whether the attack is centric or excentric.

The urine in epilepsy is variable; immediately after the fit, it usually passes in large quantity, is pale, feebly acid, and has been said to contain sugar, and sometimes albumen; urea is present in increased quantity. During the intervals between the attacks the urine is generally alkaline with an abundance of chloride of sodium or phosphates, and a deficiency, or even entire absence, of urea or urates.

The *prognosis* of epilepsy is favorable when the affection is of recent date, and is not associated with cerebral lesion; children who are liable to its attacks, frequently have them to cease with the manifestations of the peculiar changes which the system undergoes at the period of puberty; and females often have them to disappear on the birth of their first child. When the epilepsy is due to severe frights, or other powerful mental emotions, when it is hereditary, when it has affected the mind injuriously, or when it is due to deformity or disease of the cranial bones, to lesions or morbid growths of the brain, the prognosis is unfavorable.

The *pathological appearances* met with in epilepsy differ very much; indeed, it may be said that not one uniform lesion having a satisfactory relation to the convulsive affection, has been detected. Lesions of the brain similar to those observed after softening, or hyperemia of this organ, or, after paralysis, apoplexy, etc., have been observed, together with foreign growths, abscesses, etc. Similar conditions of the spinal cord have also been met with. The most frequent lesion that has been observed is hypertrophy and increased density of the brain, which Ferrus states are always present. Van der Kolk states that he has found an enlargement of the capillary vessels, and a granular degeneration of the medulla oblongata almost invariably present. Dr. S. Jackson concludes that the brain is indubitably the seat of epilepsy. Dr. Wright, of Baltimore, observes,—“From the result of all the dissections I have hitherto prosecuted, to discover the cause or condition predisposing to epilepsy, or the kind of lesion by which that form of disease had involved a fatal issue, I am led to the inference that the sensorial irritations exciting epileptic phenomena, are more frequently dependent on organic degenerations of the brain or its membranes, than is generally supposed or admitted.” Dr. Boyd, of England,

has found as an almost constant lesion, an inequality in the weight of the brain, one cerebral hemisphere being heavier than the other. Dr. Wenzel, of Mayence, has also found almost invariably a lesion of the pituitary body and pineal gland. Various morbid conditions of the spinal cord have also been recorded.—When the affection is reflex, no cerebral or spinal lesion may be present, unless the severity of the convulsions, their frequency, and long duration have ultimately induced them.

The *treatment* of epilepsy is based entirely upon general principles, there being no specific for it, and is of two kinds, viz.:—to arrest the convulsions, and to prevent their return by removing their cause, or, by curing the affection giving rise to them. During the attack the patient should be placed as speedily as possible in a position calculated to protect him from injury, and, if possible, a cork, or wedge-shaped piece of soft wood, or a small roll of leather should be placed between the molar teeth, in order to prevent the tongue from being bitten,—but there is no necessity for interfering with the movements of the patient, further than to prevent him from injuring himself. All cravats, cloths, or ligatures around the neck should be removed or loosened. A cloth moistened with cold water may be laid upon the neck and upper part of the chest, being frequently renewed, or, in its stead, cold water may be poured upon these parts. To give medicines at this time, will, as a general rule, be useless; but, in very violent cases, a finger may be placed in one corner of the patient's mouth, and the lips be drawn outwardly so as to enable the practitioner to gradually pour a dose of the Compound Tincture of Lobelia therein, and the greater part of which will be certain to reach the stomach. The dose should be according to the age of the patient, a tablespoonful for an adult and half a teaspoonful for a child a year old; and, if the convulsions continue, the dose may be repeated every ten or fifteen minutes. When the attacks happen in the night, the application to the neck of a cloth wet with cold water, either through the whole night, or just before the period when the attack occurs, will frequently prevent a paroxysm. When premonitory symptoms are present, the fit may often be prevented by compressing the carotids for a minute or so; the compression should be circumscribed so that the return current in the jugular vein be not interfered with.

But the chronist will be called upon more frequently to treat the patient during the inter-paroxysmal condition, with a view to effecting a permanent cure, if possible. Before attempting the treatment, he must first endeavor to ascertain whether the case be

centric or reflex; if the first, what is the peculiar character of the lesion; and if the latter, from what source the external irritation proceeds.

If the epilepsy be due to depression of the skull from injury, to a spicula of bone pressing upon the brain, or, to bony excrescences the only mode of cure is to trephine and remove the obnoxious portion of bone; subsequently strengthening the brain and nervous system by tonics and nutrients. Instances are on record where an operation of this kind has at once removed epilepsies which had existed for several years. In one case, where the epilepsy was connected with gastric derangement, but remained obstinate under all treatment, a constant headache being present—a piece of bone taken from that part of the head where the pain was the most acute, effected a cure; the portion of bone removed, was carious, spongy, and thickened.

If the epilepsy be produced by worms, dentition, uterine derangements, etc., these must first be removed, and, if the epilepsy still continues, then employ the means hereafter named for the convulsive affection. In every case, indeed, when the external cause of the epilepsy can be ascertained, this should be removed if possible, by appropriate measures, in connection with means to allay nervous irritability, and to strengthen the nervous centers. If from a persistence of the cause of the fits, as, masturbation, or, if from repeated and violent seizures, we discover symptoms of cerebral disorder, the proper means must be pursued to cure this, using such means, as have been heretofore recommended in chronic cerebral and spinal diseases, in conjunction with the treatment for the convulsive affection. And similar measures will be required if the epilepsy has its origin in some cerebro-spinal lesion. If anemia be present, iron will be indicated; if hyperemia, or arterial excitement, sedatives, as, *Digitalis* *Gelsemium*, etc., will be required.

Dr. Brown-Sequard is of the opinion that among epileptic patients there exists a certain peripheral spot, which may or may not be the point of departure of an aura, and which spot, when irritated, gives rise to an epileptic attack; he adduces a number of facts in support of this opinion, and then observes:—"On one side, therefore, we find that an irritation coming from the skin or a mucous membrane may produce fits without being felt; whereas, on another side, when there is the feeling of aura epileptica, the variety of the sensations, and their feebleness, often show that it is not they which cause the fit, so that we must admit that even then it is a peculiar, unfelt irritation which produces the attack.

In many animals, as I have tried to prove, it is not the pain caused by pinching the skin of a part of the face and neck which produces the fit, but a *peculiar kind of irritation*. Perhaps the special irritation which generates a fit gives sometimes a sensation quite special also, and which can not be described. If we take notice of these three sets of facts—first, that there are cases of epilepsy in which an irritation arising from the skin, or from the neighboring parts, may cause fits without being felt; secondly, that by pressure or galvanism we may produce in a part the kind of unfelt irritation which causes fits; thirdly, that such a part being found, epilepsy may be cured by either the application of ligatures, the section of a nerve, or cauterizations, etc., it becomes evident that it is of the greatest importance to try to find out in epileptics who have no aura epileptica, if there is not a part of the skin or muscle from which arises an unfelt irritation causing the fits. To ascertain the state of things in this respect, various means may be employed. If the fits are frequent, and if they come at regular times, it will be found, by placing tight ligatures around the limbs, whether the attacks are due to an irritation coming from these parts or not. (We may apply ligatures to all the limbs, alternately and successively, beginning at the upper part of each limb, and then by degrees shifting the compression downward, if necessary, even to the fingers and toes.) Among other means of detecting the existence or absence of a peripheric irritating cause of the fits, are the following: pressure upon various parts of the body; the application of localized and powerful galvanic currents; the application of ice, and of a wet and warm sponge, etc. If any part is the seat of a pain, even if this pain seems to have no relation with the fits, it will be necessary to ascertain whether pressure, galvanism, etc., applied upon this part produces an attack. If it is in a limb that a pain exists, a ligature will decide the relation of the painful spot with the fits. In cases where there is a cramp in some of the muscles, or in one only, at the beginning of the fit, the inducement of a cramp by galvanism might decide if the attack is due to the irritation of the sensitive nerve of the contracted muscle, or if the cramp is nothing but a manifestation of the attack. If the initial cramp exists in a limb, an elongation of the contracted muscle, or a ligature might lead to the solution of the question.”

In these cases, the application of a ligature around the limb from which the aura arises, is recommended; the ligature should be worn constantly around the limb, and tightened immediately as soon as the warning aura is felt,—this frequently prevents the fit,

and prolongs the intervals between them. When there exists a pain, or a peculiar sensation proceeding from some part of the body, just before the fit, or when the peculiar spots of irritation have been discovered, he advises destruction of the sensitive portion of the surface by actual cautery, and, if this does not succeed, a cure may still be effected by a section of the nerve or nerves going to the sensitive part of the skin. He thinks the best means of treating epilepsy is by the application of a series of moxas along the spine, and particularly to the nape of the neck.

When the epilepsy remains after having removed the external irritation or the disease accompanying the convulsive affection; when symptoms of cerebral lesion are present; or when the epilepsy is obstinate, or, its causes obscure, in addition to the treatment for accompanying symptoms, when required, I have derived the most advantage from the following course: Take of Iodine forty-eight grains, Extract of Belladonna twenty-four grains, Sulphate of Quinia three drachms, Alcoholic Extract of Black Cohosh three drachms; mix thoroughly together, and divide into ninety-six pills, of which one is to be taken every night and morning. These pills should produce a slight pain in the head, a heaviness, or giddiness, and which should be kept up constantly, but not too severe, regulating the dose according to the effects. During the day the following may be taken: Take of Bromide of Potassium one ounce, Water six fluidounces; dissolve. The dose is a teaspoonful, to be repeated three times a day, about two hours after each meal. In conjunction with these remedies a Compound Tar Plaster should be worn alternately upon the nape of the neck and the sub-occipital region, and then upon the lumbo-sacral region, and so on, continuing it in one place for several weeks before changing it to the other. But should this increase the attacks or cause much depression, the plaster will have to be omitted, and in its stead employ Firing, or the application of stimulating and rubefacient applications along the whole course of the spinal column.

In many instances, instead of the internal measures recommended above, I have found the following more beneficial: Take of bruised Stramonium Seed, Assafetida, Powdered Black Cohosh Root, Lupulin, each, one ounce, Spirits or Whisky one quart. Macerate for fourteen days and filter; the dose for an adult is a tablespoonful three or four times a day, about an hour after each meal. In connection with this use the following pills: Take of Prussiate of Iron, Sulphate of Quinia, Alcoholic Extract of Black Cohosh, each, four scruples; mix thoroughly together, and divide

into forty-eight pills, of which one may be given for a dose, repeating it three times a day, about an hour previous to each meal. Of course, this will not answer where there is any organic cerebro-spinal lesion, unless measures be at the same time adopted to remove such lesion.

Many other remedies have occasionally proved successful in the reflex variety of epilepsy, and also, sometimes, when it arises from functional cerebral lesion; some of them I will name: The Compound Pills of Valerian; the Compound Tincture of High Cranberry; Tincture of Poison Oak; Ice-plant; Peony; Blue Cohosh; Skunk Cabbage; Rue; Masterwort; Round-leaved Pyrola; Lady's-slipper; Gelseminum; Mugwort Root, in doses of from fifty to seventy grains, in some warm drink; Extract of Scutellaria Geniculata; Extract of Cotyledon Umbilicus (Napplewort), in doses of five or six grains night and morning; Acetate of Strychnia, one-fiftieth of a grain, repeated three times a day; Oxide of Zinc in large doses; Valerianate of Zinc one-half grain, repeated two, three, or four times a day; Digitalis, when much arterial excitement is present; Sulphate of Zinc, two grains daily, in solution; Glohoin; Lactate of Zinc, four to eight grains repeated three times a day; Oxalate of Cerium, in those cases only where an aura is present; Ammoniacal Sulphate of Copper, one-half grain twice a day, increasing the dose one-sixth grain every other day, in cases of purely nervous epilepsy without complication; Oxide of Silver; Nitrate of Silver; Chloride of Silver, etc. The objection to the Nitrate of Silver is that it is very apt to effect a permanent discoloration of the skin. Atropia and the Valerianate of Atropia, the latter in doses of $\frac{1}{132}$ of a grain every twenty-four hours, and very gradually increased not to exceed $\frac{1}{33}$ of a grain in twenty-four hours, suspending its use as soon as the vision is disturbed, and resuming it when this symptom has disappeared for a few days, has likewise been highly spoken of.

Dr. Radcliffe recommends Phosphorus twelve grains, dissolved in Almond Oil one ounce, by the aid of heat or warm water; the dose is from five to ten minims, and may be given in Cod Liver Oil, Elixir of Bark, etc. He also advises a continuous current of galvanism to be kept up along the spinal cord by means of a Pulvermacher's galvanic belt. The following has also been recommended: Take of Phosphate of Zinc four grains, Diluted Phosphoric Acid twenty minims, Tincture of Cinchona, of Valerian, or of Conium, etc., half a fluidrachm; mix for a dose; to be repeated twice or three times a day.

The following pills have also been found very serviceable in

simple, uncomplicated epilepsy: Take of Phosphate of Zinc two drachms, Prussiate of Iron forty grains, Sulphate of Morphia five grains, Alcoholic Extract of Black Cohosh, a sufficient quantity to form a pill mass; divide into sixty pills. The dose is one pill, to be repeated three times a day. Also, Oxide of Zinc one drachm, Extract of Conium, one scruple; mix, and divide into twenty-four pills—to be taken the same as the preceding. Likewise, Citrate of Iron and Strychnia one drachm, Syrup of Black Cohosh six fluidounces; mix. Dose, a teaspoonful three times a day.

Tracheotomy has been proposed, but its necessity is very doubtful; ligature of the common carotid has been tried and proposed, but this is apt to give rise to softening of the brain; cauterizations with caustic potassa on each side of the dorsal and cervical vertebrae, and repeated every five or six weeks, have proved very successful; and so has, likewise, the actual cautery applied to the top of the head along the sagittal suture, five or six applications effecting a cure—the cauterizing iron was about two lines in diameter, and the whole thickness of the skin was implicated.

The bowels should be kept regular in epilepsy, but never purged, except under extraordinary circumstances; and instead of ordinary laxatives, Sulphate of Quinia, Extract of Nux Vomica, Strychnia, and even Opium will be found to act the most beneficially, especially in anemic cases. In some cases, these agents will be rendered still more efficient by the addition of Rhubarb, or small quantities of Podophyllin. Extract of Nux Vomica half a grain, combined with Extract of Gentian one grain, for a dose, and repeated three times a day, will often rectify the sluggish state of the bowels. The skin should be attended to daily, by bathing, friction, etc., and in many cases, the use of the cold shower bath daily will be very serviceable. Everything should be adopted in the hygienical treatment to allay irritation, and to promote the health and vigor of the entire system. The diet should be moderate, (for epileptics are generally great eaters), nourishing, and easy of digestion, avoiding fats, acids, liquors, and food disposed to cause gastric acidity, constipation, or flatulency. Animal food may be used in moderation; coffee and tea should positively be abstained from, and in their place make a beverage of the following: Take of Skullcap, Peony, Valerian, Peach Leaves, each one ounce, Sassafras Bark three ounces; mix together. A teaspoonful of this may be infused in half a pint of boiling water, sweetened, if desired, and be made use of as a common drink, either warm or cold. All sources of mental irritation must be avoided, and, for this reason it will frequently prove advantageous to remove the

patient from his ordinary business, or his daily associations. Sexual intercourse must positively be prohibited. Regular, but moderate exercise of the voluntary muscles will be very beneficial, yet the patient should be careful to avoid dangerous places, lest a fit should come on, and he be precipitated to the ground—as, standing or working upon houses, ladders, precipices, or near deep ponds, rivers, wells, etc. An inactive, sedentary life, increases the morbid predisposition, and renders the consequences of the fits more deplorable. Out-door work, as agriculture and gardening, will especially be found of great utility. The hours should be properly regulated for sleeping and rising; exposures to cold, or sudden changes, violent passions, should be carefully guarded against. The head should be kept cool; the neck be kept free from tight cravats or other ligatures; late suppers should be dispensed with, at least three hours being allowed to intervene between the supper and bed-time; and during sleep the patient should always lie with his head high, to assist the circulation of the blood through the brain, and should as much as possible avoid lying upon his back. Intellectual employment requiring deep thought is injurious. Moderate reading, drawing, music, light composition, and the elements of chemistry, botany, physics, etc., afford great satisfaction, and sustain the moral powers instead of exhausting them. Variety of occupation, intermingled with cheerful society, and amusing relaxations, will prove very serviceable.

CHOREA.

St. Vitus's Dance, or Chorea Sancti Viti, is an affection characterized by a singular mixture of convulsive motions, partial paralysis, and tremors of the limbs, which produce the most whimsical and varied contortions, and which occur without pain. It may come on at any period of life, from one year old and upward, and is more common among females than males, in the proportion of about two and a half to one, generally manifesting itself between the fifth and sixteenth year. Although a disagreeable affection, it is seldom attended with danger, unless it be complicated with epilepsy, paralysis, cardiac disease, or some other serious malady. It may affect only one part of the system, or more frequently, several. The disease, if not checked by proper treatment, may continue for years.

The *causes* of Chorea are not satisfactorily understood, and, as with epilepsy, authors disagree in relation thereto. The most

recent hypothesis is probably as near being correct as any; it is, that the nervous system is in a state of morbid susceptibility or irritability connected with imperfect nutrition of the nervous centers, which susceptibility is either hereditary or acquired, and that, in consequence of it, a peripheral irritation may produce such a functional disturbance in the nervous center as to develop the choreic movements. This peculiar delicacy of nervous organization is frequently met with among the offspring of consanguineous marriages, and is likewise common among persons subject to erysipelas, or those of strumous diathesis. Indeed, I have never yet met with a case of chorea, in which there were not some indications of strama.

From the recurring character of the convulsive motions, Dr. Elam states that there must be a stimulus acting upon the extremities of a morbidly irritable excito-motor nerve, and the influence of which is reflected from the motor centers, which respond in a more vigorous and irregular manner upon the muscular system. When the stimulus is in excess the spasms are tonic, giving rise to cramp; but when the excitability of the nervous extremities is increased, they are clonic. He notices a great similarity between chorea and neuralgia; one attacks the motor and the other the sentient nerves; both are chiefly due to external irritation, as of the intestinal or uterine systems; both are usually diseases of debility; both are relieved by tonics, and are almost incapable of relief by narcotics.

Among the exciting causes, by far the most frequent, is an affection of the mind, arising from any depressing passions, as grief, horror, and especially fright; although some writers consider that the tendency to be readily alarmed, etc., is due to the predisposition to the chorea, and that the chorea is not the result of the mental shock. However this may be, the affection may develop itself immediately, or may not be observed until weeks or even months have passed. Rheumatism is the next in order among the exciting causes, especially when it affects the heart and pericardium, giving rise to irritation of the plexus and ganglia. I have only in a few cases observed chorea to be in any way associated with rheumatic disease; and as to the bellows murmur supposed to be indicative of mitral disease, although present in many instances, it is not persistent, and may, as is well known, be due to anemia, or spasmodic action of the columnæ carneæ and the chordæ tendineæ. Irritation is another exciting cause, the result of constipation, intestinal worms, dentition, repression of cutaneous diseases, suddenly suppressed perspiration, suppression of customary

discharges, a peculiar morbid condition of the blood, uterine irritation, ovarian irritation, uterine prolapsus, the condition of pregnancy, falls, blows, excessive venery, or masturbation, as well other causes that may give rise to nervous debility or extreme irritability.

The *symptoms* of chorea are readily known. It is frequently preceded by a changeable, and often a voracious appetite, loss of sportiveness and spirits, a hard, tumid condition of the abdomen, with more or less obstinate constipation. Spasmodic movements or rather twitches of the fingers, muscles of the face, or other parts of the body, are observed, being at first very slight, but gradually increasing, and extending themselves so as to interfere with walking, speaking, and even mastication. These movements are involuntary and irregular, varying much in different individuals, sometimes affecting one complete half of the body; they frequently border upon the ludicrous, especially when the disease is limited to the facial muscles, and are very mortifying to the patient. The face may be contorted into various shapes, looking as if the individual were making "wry faces" on purpose; the head may be constantly in a state of motion, trembling, moving up and down, or occasionally drawn suddenly and momentarily to the right or left; the gait will be unsteady, or the leg may be awkwardly dragged along; the hand or arm can not be steady for a moment, but moves convulsively from one position to another, although the patient strives to prevent it. In some cases, the movements are so violent that the patient can neither sit, stand, nor lie down.

- Pain in the head is very common in these instances of excessive motion, and palpitations of the heart, if the affection be associated with rheumatism. In a few cases, there will be observed a difficulty in respiration, as well as in deglutition.

Dr. R. B. Todd observes as a pathognomonic symptom of chorea, protrusion of the tongue with a peculiar thrust to the fullest extent of which it will admit, frequently this is done by one effort; at other times, it requires two or three attempts before it can be accomplished. The retraction of the tongue is also peculiar; it is drawn back, supported and guided by the pressure of the teeth, and often very slowly, and with great caution. This symptom frequently precedes an attack of chorea. One side of the body is always more affected with the choreic movements than the other, and he considers those nuisances, fidgety, uneasy, ever-in-motion children, as being predisposed to chorea. A tendency to fall forward in descending a pair of stairs, has also been noticed as a symptom.

As the disease advances, the general health becomes more or less impaired as manifested by pallid countenance, pulse regular but feeble, impaired appetite and digestion, flaccidity and wasting of the muscles, and sometimes a debility of the intellectual powers to such a degree as to threaten idiocy; this last, however, is not necessarily present, as I have met with cases, where the disease had been in existence for twelve and eighteen years, the only mental affection being extreme irritability, the intellect remaining unimpaired. Occasionally, there may be some pain or distress present, but not as a general rule. Children laboring under chorea are very apt to be capricious, fretful, and easily alarmed; the motions becoming much more severe when they meet with any opposition or contradiction. The choreic motions are less marked, and frequently entirely suspended during sleep, while the brain is occupied in its own acts. Dilatation of the pupils is a common symptom in chorea. The urine is usually high-colored, acid, with an abundance of urates, and uric acid.

There is a form of this disease termed "Electrical or Acute Chorea" by Dr. Dubini, generally produced by fear, and characterized by movements, strikingly resembling those resulting from electrical shocks, which are always identical, constantly affecting the same muscles as at the commencement, gradually, however, implicating others of the same side also, usually the right side, the contractions of which are followed insensibly, and sometimes suddenly, by paralysis,—apoplectic stupor supervenes, and the case terminates fatally, recovery being the exception. The patient has from the first a presentiment of the gravity of the disease. No lesions explicable of the symptoms have been observed.

The *diagnosis* of chorea is not difficult; it differs from other convulsive diseases, in the spasms being clonic, continuous, and not accompanied with fever, delirium, unconsciousness, or coma. In *shaking palsy* the movements are due more to weakness and loss of muscular control than to spasmodic action. In *writer's cramp* the fingers can perform every other movement properly, except the one which has produced the affection, as writing, sewing, painting, etc. In *facial spasm*, the convulsive movements are limited to the same set of muscles, usually on one side only of the face, and are equal in degree.

A peculiar form of this affection, or, at all events, one closely related to it, consists in more or less violent bobbings of the head, repeated at intervals varying from a few seconds to an hour or two. There is a convulsive jerk of the extremities forward, and a bowing of the head with instantaneous relaxation, which may continue for

several minutes, the spasms sometimes increasing in intensity. The mind is not apt to be affected in the slightest degree. I have seen but two cases of it, both girls, one about seven, and the other eighteen years of age. Dr. West named the disease *saluam convulsions*; as far as observed children are more generally liable to it. The treatment of this singular affection consists in the administration of a purgative or vermifuge, to obviate irritation from costiveness or worms, or, if other sources of irritation be detected, to make use of the proper measures to remove them, and, at the same time, to apply counter-irritation along the whole course of the spinal column, as vesication, firing, etc., in order to subdue any meningeal or other irritation or chronic inflammation of the spinal marrow, or of the roots of the nerves, that may be present. In conjunction with this, Belladonna, Conium, or Hyoscyamus, etc., may be administered internally, with Iodide or Bromide of Potassium, or of Iron, according to the strumous, rheumatic, or anemic condition present.

The *prognosis* of chorea, as a general rule, is favorable. When the pupils dilate or contract normally in response to light or its diminution, it is indicative of returning health. When complicated with other affections of a serious and extensive character, or when the mind has become impaired, the prognosis is unfavorable. It may be proper to remark here, that when chorea is complicated with other diseases, as chlorosis, hysteria, menstrual derangements, rheumatism, erysipelas, cerebral affections, etc., these maladies must be treated in precisely the same manner as if the chorea were not present; and, after their removal or amendment, if the chorea does not disappear, it may then be more directly attended to.

The *pathological appearances* observed in chorea vary; indeed, no one organ has yet been discovered the lesion of which can be considered as decidedly characteristic of chorea. Anemic conditions are evidenced by softness, paleness, and flaccidity of the tissues; and disease of one or more organs, perhaps those giving rise to the choreic irritation has also been discovered. Cerebral softening, tubercles, softening of the spinal cord, adhesions of its membranes, etc., have also been observed, but these have been regarded as mere coincidences. M. Serres has found fatty tumor on the tubercula quadrigemina, or inflammation of the corpora quadrigemina, sometimes extending to the roof of the fourth ventricle, with blood effusion at the base of the quadrigeminal bodies.

There is no specific *treatment* for chorea; the indications are to remove all sources of irritation, as well as any existing complications, and then if the chorea still remains, adopt measures to over-

come the nervous affection. If the disorder be due to sudden mental emotion, as to fright, for instance, producing a strong impression upon a weak and excitable nervous system, the most benefit will be derived from those remedies which improve the general health, and give vigor and tone to the muscular systems, as well directed gymnastic exercises, aided by vegetable or mineral tonics, and a nourishing diet. If dentition be the exciting cause, the proper remedy is understood by every one. If worms, or accumulated feces be the source of the external irritation, vermifuges and purgatives may be administered; yet, it must be borne in mind, that continued purgation is injurious. If constipation be habitual, *Nux Vomica* or *Strychnia* will impart tone to the debilitated muscles. If the disease be connected in any way with the reproductive organs, we must select our remedies according to the nature of the functional or organic lesion of these organs. And the same measures will be required, that is, according to the indications present, and the nature of the disease, whether it be rheumatic, or be due to repressed cutaneous affections, renal disease, morbid conditions of the blood, too rapid growth, sexual excesses, exhausting discharges, etc. If it occur during pregnancy, anodyne injections will prove very serviceable.

The remedies which I more commonly employ in the treatment of chorea, for the purpose of overcoming the nervous affection, as well as any anemia, or tuberculous or strumous disease that may be present, are as follows: Take of Iodine fourteen grains, Iron by Hydrogen forty grains, Sulphate of Morphia four grains, Alcoholic Extract of Black Cohosh forty grains; mix well together, and divide into forty pills, of which the dose is one pill, to be repeated three times a day.

Counter-irritation, vesication, or the Compound Tar Plaster, applied to the nape of the neck and sub-occipital region, will almost always prove serviceable, especially in cases where pain exists in the neighborhood of this region. The counter-irritation with liniments, etc., should always be applied along the whole course of the spinal column, and be repeated at least twice a day. The Tar Plaster will, at first, cause an increase of the movements, but they will subside after a few days; but if it causes great depression its use must be omitted. It may likewise be placed over other parts of the spinal column where there is pain with or without pressure or percussion.

Other compounds, however, will also be found successful, and may be administered according to the indications present, as anemia, nervous irritability, vascular excitement, restlessness, etc., as follows:

1. The Compound Pill of Black Cohosh. 2. The Compound Pill of Valerian. 3. The Compound Tincture of High Cranberry Bark. 4. In cases where there is a tendency to numbness or paralysis, a pill, to be repeated three times a day, composed of Extract of Belladonna one-eighth of a grain, Strychnia from one-twentieth to one-fiftieth of a grain, Alcoholic Extract of Black Cohosh two grains; mix, and make a pill. 5. Sulphate of Zinc two grains, Extract of Indian Hemp three-fourths of a grain, Alcoholic Extract of Black Cohosh half a grain; mix, and form one pill. To be given in doses of one pill, and repeated three times a day. 6. Take of Horse-radish Root, White Mustard Seed, each, four ounces, hard Cider two quarts; mix, and let the mixture stand several days before using. The dose is from half a wineglassful to a wineglassful three times a day. In conjunction with this, give from half a teaspoonful to a teaspoonful of a preparation of Port Wine one pint, in which has been macerated Russian Castor one ounce; repeat the dose three or four times a day. This has effected many cures.*

* Miss Sarah H——, aged 19, was afflicted with chorea of sixteen years standing, during which time, as her friends informed me, she had been under the care of several eminent physicians of this country and Europe, had been bled, cupped, blistered, mercurialized, taken nitrate of silver, ammoniated copper, etc.; cold shower baths had been used until they caused convulsions; and music, so highly recommended by some writers, was of no avail; in fact, I was informed that the invariable result of treatment which she had undergone was an aggravation of the symptoms, and they were almost fearful to subject her to any new treatment. I found her excessively debilitated, the mental energies somewhat impaired, the thumbs and fingers incessantly in motion, the head constantly shaking about, and every two or three minutes the mouth would be rapidly and convulsively drawn to one side, accompanied with an audible noise, somewhat resembling that produced by sucking in air. When seated, her feet were not in motion, but while walking they were involuntarily thrown in various directions, yet not to interfere with locomotion, and the toes of one foot dragged upon the ground, so that she required a new pair of shoes every week. In addition, she labored under chronic erysipelas, had an almost insurmountable repugnance to anything like medicine, and much persuasion was required to induce her to try a new course of treatment.

To relieve gastric acidity and constipation, the Compound Syrup of Rhubarb and Potassa was given, three times a day; and she was placed upon the following treatment: A pill was given every two hours, composed of Alcoholic Extract of Skullcap two scruples, Alcoholic Extract of Black Cohosh one scruple, Alcoholic Extract of Nux Vomica one and a half grains; mix, and divide into forty pills. The Nux Vomica was gradually increased in this prescription to four or five grains, then decreased, and so on alternately. Fats, acids, coffee, and tea were prohibited, a warm infusion of Peach Leaves and Skullcap being substituted for the latter. The surface was bathed weekly with a warm, weak alkaline solu-

Among the host of remedies which have been used in this disease, the following seem to rank the highest among old school and other physicians: Strychnia, but it often aggravates the convulsive motions, and requires great care in its administration; Precipitated Carbonate of Iron in drachm doses, repeated three times a day, given alone or in Port Wine; Arsenic, or Fowler's Solution is, by some, considered almost a specific; it is at best a doubtful remedy, and is not employed by physicians of the school to which I belong. Prussiate of Iron, which may be combined with some antispasmodic vegetable extract; inhalation of Chloroform, repeated once or twice a day,—when first used the movements are increased, but as the inhalation goes on, a calm succeeds; *Veratrum Viride* is said to have effected most decidedly beneficial results; Sulphate of Aniline, in doses varying from half a grain to two grains a day, has been highly spoken of,—the dose is given in solution with a drop or two of Sulphuric Acid, and should be repeated three times a day; Iodide of Zinc is advised in strumous cases; Ammonio-Sulphate of Copper in doses of from half a grain to a grain, repeated three times a day; Hypodermic injections of Sulphate of Morphia, Sulphate of Atropia, Sulphate of Quinia, or other tonics and anodynes; the root of *Artemisia Vulgaris*; *Sanicle Root*, or *Sanicula Marylandica*, is frequently very valuable, it may be used in powder, infusion, fluid extract, or alcoholic extract; faradization of the skin over the affected parts, but not of the muscles themselves, etc.

The bowels should be kept regular; the urinary secretion be properly attended to; every night and morning friction with a coarse towel or flesh-brush, so as to produce an agreeable glow on

tion; a spirit-vapor bath used every two or three weeks; and exercise in the open air advised, with an avoidance of crowded assemblies.

In about ten months, under this treatment, all involuntary movement ceased, save that of the thumbs. The following pill was now ordered, in addition: Take of Red Oxide of Iron twenty-four grains, Iodine six grains, Sulphate of Quinia twelve grains, Extract of Liquorice a sufficient quantity; mix, and divide into twelve pills, of which the dose was one, to be repeated three times daily, for three weeks; after which, one pill night and morning.

Soon after the use of these pills, she commenced improving rapidly, her appetite became regular, as well as the bowels; her strength gradually returned, and her mental improvement was very marked; and the erysipelatous affection, which appeared from time to time, did not again manifest itself. In two years this treatment was followed by a permanent cure. I believe she would have recovered much sooner, were it not that during the treatment she was attacked at one time with pneumonia, and again with inflammatory rheumatism, accompanied with severe pain in the head and delirium, and, shortly after this, with an obstinate acute hepatitis. Twenty-four years have now passed since the cure, and there has been no return of the chorea.

the surface of the body, should be performed by a second person ; the body should be bathed once or twice a week with a weak alkaline solution. In some cases the shower bath may be useful, but care must be observed in its employment, as I have seen the disease very much aggravated by it. The diet should be full, nutritious, and easy of digestion, avoiding acids, grease, and the use of coffee, tea, or liquors in excess. Moderate exercise should be regularly taken every day, and the patient should avoid all circumstances or assemblies calculated to mortify or excite, and thus increase and perpetuate the convulsive motions. And all excesses, masturbation, etc., must positively be prohibited.

There is one thing to which I would especially call attention ; and that is, a white coat upon the tongue, with paleness of the body of the tongue, indicative of gastric acidity and anemia ; this is very frequently met with in chorea, and for which I have found the Compound Powder of Charcoal, with a few grains of Ginger to each dose, to be a most excellent remedy. Indeed, until this symptom becomes materially improved, not much benefit will be derived from the other treatment employed.

CATALEPSY.

Catalepsy is a rare affection ; it consists of a sudden suspension of sense, intelligence, and voluntary motion, without any fever necessarily ; the muscles being sometimes rigid, and at others movable, keeping the position in which they were at the moment of attack, or in which they may subsequently be placed. The condition of unconsciousness continues for a longer or shorter time, from a few minutes to several hours, rarely for several days, and when it subsides the patient presents the condition of health usual to him, but has no recollection of events that transpired around him during the cataleptic state. Some cases have, however, retained consciousness during the seizure, and have had a perfect cognizance and recollection of what was going on around them. Some forms of catalepsy are termed "trance," and others "ecstasy." The disease is more common among hysterical females, and at the age of puberty.

The *causes* of catalepsy are not well understood, though, from the character of the symptoms, it appears to be an affection of the cerebral lobes and spinal cord. It is excited into action by painful mental emotions, gastric or menstrual derangements, worms, excesses, intense study, etc., as well as by certain injuries.

In a few instances premonitory *symptoms* are present, as, cephalalgia, vertigo, flushed face, pain in the chest, lassitude, yawning,

forgetfulness, depressed spirits, etc. More commonly, however, the attack is sudden, the patient remaining in the position he held at the time, being unable to move, and if a limb be moved by another person into any position, or if an eye be opened, etc., it remains so, fixedly. I have, however, witnessed instances where patients would move about and converse with others, having no recollection of the events upon recovering from the cataleptic condition. There is almost always a partial or complete suspension of the senses. Should the patient be occupied in conversation, for instance, or any other continuous act, when the attack occurs, he may finish the interrupted sentence, or continue his acts, as soon as restoration happens, without being apparently aware that any interruption has taken place.

As to the *prognosis*, catalepsy is seldom dangerous, and is occasionally followed by the cure of previously existing disease of the brain and nervous system, as, epilepsy, hysteria, etc. In a few instances, it has terminated in epilepsy, apoplexy, melancholy, etc., and proved fatal ultimately. Any violent efforts made to recover the patient from the cataleptic state, is improper, and apt to induce serious results.

The *diagnosis* of catalepsy is not difficult. It may be determined from *apoplexy* by the stertorous respiration, the relaxed and flexible condition of the limbs, the congestion of the head and face, and the paralysis, which are common to apoplexy, but are absent in catalepsy. From *asphyxia*, by the total suspension of respiration and circulation, and the livid color of the face and lips in this affection. From *death*, by the application of the stethoscope over the region of the heart, by detecting pulsation at some part, by the temperature of the body, the unrelaxed state of the sphincters, and by the condition of the cornea.

Catalepsy rarely requires *treatment* during the attack, unless certain symptoms demand it, as, determination to the head, feeble pulse, cardiac palpitation, etc. Ordinarily, it will be better to allow the patient to recover from the paroxysm spontaneously. I have seen mesmerizers make their mesmeric passes for a few minutes over cataleptic patients, and immediately after, either awaken them, or be able to converse with them freely, the paroxysm still remaining; and I have seen the habit of night-somnambulism wholly destroyed by the same means—but I do not profess to understand how or why this peculiar influence was effected.

When catalepsy occurs frequently, the treatment during the intervals between the paroxysms should be directed toward strengthening the nervous centers and restoring them to a normal condition

by the means heretofore advised. Congestive or irritative symptoms existing in any of the organs, and especially of the uterus, should be promptly removed by the proper treatment; functional uterine derangement will require uterine tonics; and anemia must be met with chalybeates. It will also be proper to take into consideration the diathesis of the patient, as, predisposing to scrofula, rheumatism, extreme nervous susceptibility, etc., and adopt remedies in accordance therewith. The bowels, kidneys, and skin must be maintained in as normal a condition as possible, moderate exercise should be taken daily, and the diet should be adapted to the wants and condition of the system. All exciting causes must positively be avoided, and those that are present, as, worms, suppressed eruptions, etc., must be removed by appropriate means.

Should any soreness or tenderness be discovered along the vertebral column, Croton Oil Liniment, or other strong counter-irritant should be kept applied over the tender points, in connection with the other treatment. Half-grain doses of Nitrate of Silver, repeated three times daily, are stated to have cured catalepsy.

NEURALGIA.

Neuralgia is the term applied to a paroxysmal painful affection of the nerves, which more commonly has its location in one nerve, and which is not due to inflammation, nor to any appreciable structural change of the nerves. The pain is more or less violent, most generally occurring in the cerebro-spinal nerves, in paroxysms of irregular duration, and after irregular or regular intervals. The pain may be seated either in the trunk of a nerve, or along its branch; according to Valleix, the "focal points," or points more especially liable to neuralgia, and from which the severe pains radiate, spontaneously, or from exciting causes, are, 1, at the place where the nervous trunk emerges from its bony sheath, as, at the supra-orbital foramen, the infra-orbital foramen, the ischiatic notch, the crural arch, etc. At this point, wherever it may be situated, the affected nerve will be found tender to pressure, whether the neuralgic pain be felt here by the patient, or at some other point along the course of the nerve.

2. The second focal point or center of pain, is where a nervous branch passes out through a muscle, for the purpose of being superficially distributed in the integuments; as, for instance, behind the mastoid process, at the place of the posterior branch of the second cervical nerve, or at the superficial points of the inferior spinal nerves.

3. At the point where the terminal nerve-twigs or branches expand to be lost in the integuments.

4. At the point where the trunk of the nerve suddenly becomes more superficial in its course, running along near the integument; as, at the superficial point of the ulnar nerve as it passes the inner condyle.

This knowledge, although imperfect, is of considerable importance, as it enables us to ascertain in most instances the exact location where moderate pressure gives rise to tenderness.—Not unfrequently we may have a neuralgia of the ganglionic or sympathetic nerves, which may acquire an abnormal sensitiveness from certain irritating causes, as, vascular excitement, functional derangement, etc.; but the pain is not so well marked as in true neuralgia, and does not present, as an accompaniment, a proportionate degree of constitutional disturbance.—Neuralgia may be located in any part of the body, though more frequently in the region of the head. It affects males and females equally, the former being more liable to the sciatic and the crural forms, and the latter to the dorso-intercostal and the lumbar. It rarely proves fatal, though it may ultimately be followed by some serious disease, yet this is not common; though when severe and of long duration, the patient eventually dies, worn out from the oft-repeated shocks, and the more or less constant nervous irritation. Its duration is very uncertain, and a person once attacked by it is liable to subsequent attacks at any time when exposed to the exciting causes, even though the original affection may have been removed by proper treatment.*

* M. Valleix has indicated the following points as neuralgic centers, much suffering being produced spontaneously or by pressing upon them, sometimes the slightest pressure occasioning a violent paroxysm:

In *facial neuralgia*, the points are, the supra-orbital foramen; the eyelid and edge of the orbit; within and below the internal canthus; the eyeball; the infra-orbital foramen; the malar bone; the teeth and gums; the upper lip; the palate; the temple; the temporo-maxillary articulation; the mental foramen; the tongue; the lower lip; behind the mastoid process at some point between it and the vertebral column; and at the anastomosis of the branches of the trigeminus, above the parietal protuberance, from which point the pain radiates over the occiput and face.

In *cervo-occipital neuralgia*, the painful points on pressure are, between the mastoid apophysis and the first cervical vertebra; near the parietal protuberance; at the emergence of the superficial cervical nerve; upon the mastoid process; and upon the concha.

In *cervico brachial neuralgia*, the most important focal points are, at the emergence of the posterior branches from the muscles at the sides of the inferior cervical vertebra; at the superficial point of the axillary plexus; upon the spine of the scapula; around the neck of the humerus, and between the integuments and

The *causes* of neuralgia are not well understood; in many instances no attributable cause for the attack can be discovered. The long-continued action of cold, of cold and moisture, sudden exposures to cold, wearing damp clothes, continued exposures to excessive heat, or to irritating vapors, which derange the capillary circulation, mechanical injuries, pressure upon nerves from tumors or other causes, cutaneous irritations, uterine irritation, inflammation of mucous membranes, cerebral or spinal affections, gastro-intestinal

the deltoid muscle; along the course of the internal cutaneous nerve on the inner side of the arm, especially between its anterior and posterior branches; between the two heads of the pronator radii teres where the median nerve passes, and at the lower part of the fore-arm where the median nerve furnishes the palmar cutaneous branch; behind the inner condyle, at the wrist, where the ulnar nerve or its branches are superficial; and, upon the musculo-spiral nerve as it winds round the spiral groove, and furnishes its cutaneous branches. Behind the internal condyle is the most common center of pain, the other usual points being in front of the wrist, in front of the elbow, and in the axilla, and more frequently in the course of the ulnar nerve.

In *dorso-intercostal neuralgia*, the principal points are, over one or more of the intervertebral foramina; at the center of one or more of the intercostal spaces; and near the margin of the sternum, or of the upper edge of the rectus abdominis, or of the external oblique.

In *lumbo-abdominal neuralgia*, the focal points are, at the superficial parts of the posterior branches of the lumbar; the middle of the crest of the ilium, (iliac); immediately above the external abdominal ring, (hypogastric); near the center of Poupart's ligament, (inguinal); the testicle or labia majora, (scrotal or labial).

In *crural neuralgia*, the points are, in the course of the anterior crural nerve or its branches; at the origin of the crural nerve, at the lumbar plexus; at the groin; near the center of the sartorius muscle; over the inner condyle of the femur; around the inner ankle or malleolus; and at the internal side of the sole of the foot, along the integument of which the internal saphenous branch of the crural nerve sends filaments as far as the great toe.

In *sciatica* or *femoro-popliteal neuralgia*, the points are, at the posterior superior spinous process of the ilium; the center of the iliac crest; the superior portion of the sciatic notch; the great trochanter; the ischiatic tuberosity; the middle of the thigh; near the insertion of the biceps, as well as along the whole of the thigh; the knee; the outer portion of the ham; the head of the fibula; the whole length of the fibula; the center of the fibula; the external malleolus; the upper part of the posterior surface of the lower leg; and the foot and toes.

M. Troussseau, in a clinical lecture on neuralgia, observes:

"If neuralgia occupied the branches of the trifacial, it was always at the point of emergence of the ophthalmic branches, and of the superior maxillary and the inferior maxillary, that the pain was felt most acutely; then came the frontal point where pain rarely failed; then the parietal point where it was more frequently wanting; lastly, the occipital nerve, although having no relation of origin with the trigeminal, is almost always affected. An extraordinary thing—inexplicable, but invariable in all the cases which we have carefully observed and noted—is that, whether the trifacial were alone attacked, or the occipital nerve

derangements, syphilis, gout, anemia, blood-disease, profuse hemorrhages, caries of the teeth, want of proper nourishing food, and malaria, have all been named as exciting causes of neuralgia. Cold and dampness being undoubtedly the most frequent among these causes. Indeed, neuralgia may be produced by any cause that deranges the molecular nutritive actions of the nervous structure, so as to impair its function, and give rise to nerve debility, or diminution of the vital power and functional action of the nerve.

The principle *symptom* of neuralgia is the pain, which usually comes on suddenly, is of a lancinating, agonizing character, shooting along the course of the affected nerve like an electrical shock, frequently feeling as if red-hot wires were thrust into the part, and after the pain passes away a numbness in the part remains for some time. These pains will commonly be found seated at one or more of the points referred to by Dr. Valleix, often passing from one to the other in rapid succession; or, they may radiate from those points at which pressure gives rise to pain. Again, they may dart from one focal point or pain-center to another, without any suffering whatever in the intermediate portion of nerve; and, in many instances, instead of shooting along the course of the nerve in the direction of its trunk, or superficial ramifications, it will dart in a direction opposite to that of the affected nerve. Although, especially in severe neuralgic attacks, there may be tremors, cramps, or spasmodic movements of the muscles whose nerves are affected, yet no heat, redness, or swelling will be present, these existing only when there is an inflammation of the nerve. Sometimes, previous to the sudden attack of acute pain, slight sensations of heat will be experienced in the part affected, or itchings, numbness, etc., which more or less rapidly augment in severity.

The pain may continue for from a minute or two to several hours, and may reappear at regular or irregular periods, the intervals between which may vary from twelve or twenty-four hours to several weeks, months, or even years. In some cases, there

simultaneously affected, pressure on the spinous apophyses of the first two cervical vertebrae was *always* very painful, and in a certain number of cases immediately awakened the pain in the affected nerves. If the nerves of the brachial plexus were attacked, invariably pressure over the spinous apophyses of the last cervical vertebrae produced pain, and it was the same when we explored the vertebral column in the case of intercostal, lumbar, and sciatic neuralgia." The spinous apophyses being painful at a point nearly corresponding to that at which the nerve emerges, and not unfrequently the pain extends a little higher up the vertebral column.

exists no pain during the intervals, while with others there is a constant dull pain, of a very annoying character which continues persistently, and which is augmented with each paroxysm; or, this constant dull pain may be the only symptom of the neuralgia. The pain of neuralgia may be often excited by the most trifling causes, as, certain movements of the patient, the use of certain articles of diet, etc. As a general rule, pressure upon the affected nerve will produce pain in one or more of the focal points indicated by Valleix; this pain may be merely a temporary increase of the persistent dull pain complained of; it may consist of painful twinges along the course of the nerves; or it may be of a lancinating, darting character, like those which occur during the paroxysms; and, in some cases, the slightest degree of pressure upon one of these pain-centers will give rise to the most terrible neuralgic paroxysms.

A peculiar feature attending the pain produced by pressure is, its limited extent of surface, frequently being confined to a space not exceeding one-fourth of an inch in diameter, and terminating so abruptly, that at a distance of even one-twelfth of an inch from the margin of this diameter, ordinary pressure would not develop any indications of morbid sensibility. Hence, great care must be taken in the examination of patients, for the purpose of determining the location of the focal neuralgic points, to carefully press with the finger-end not only upon the painful part as located by the patient, but also upon the whole course of the nerve-trunk and its chief ramifications; by this means we may excite pain in parts where it does not appear spontaneously, and thus ascertain the extent of the neuralgic affection. This pain from pressure is more severe during the paroxysms, and less so in the intervals, and almost invariably exists at those points where pain occurs spontaneously. It must also be recollected that this pain from pressure is not constant; an examination to-day may not excite pain, but an examination to-morrow of the same point may find the pain or tenderness present; or, pain produced at a given point will not be re-excited by subsequent pressure until a certain interval has passed, when the point again assumes its usual morbid sensibility. Undoubtedly there are some cases in which there will be no pain at all on pressure; and, again, this pain may be observed only during the paroxysm, and wholly disappear during the interval. The most usual kinds of neuralgia are as follows:

1. *Facial Neuralgia*, Neuralgia Faciei or Tic Doreux, which is frequently met with, is seated in some one or more of the ramifications of the trifacial or fifth pair of nerves. We must carefully

distinguish the spontaneous pains from those produced by pressure. Instead of following the course of the nervous filaments, as some writers suppose, the spontaneous pain occupies very variable points, often multiple. In twenty cases, the spontaneous pain existed in the temple nine times, in the cheek six times, in the forehead six times, in the eye five times, in the gums three times, at the ala of the nose in two cases, in the lip once, and once at the point of emergence of the infra-orbital nerve. The pain on pressure existed eleven times at the point of emergence of one or of two branches of the trifacial nerve, twice at the temple, once at the nasal ala and at the lip. As to the exact location of the pains, it was six times at the supra-orbital, six times at the infra-orbital, and once at the mental foramen. .

These pains, both the spontaneous and those elicited by pressure, are apt to be very mobile, often rendering local medication of no avail; thus, the pain which, at the commencement of the paroxysm, was at the occiput, may pass to the scalp, then to the temple, and fix itself on the jaw, or at the temporo-maxillary articulation. At other times, the pains may pass from one side to the other; at one time it may occupy the dental branches or the teeth, at another the occiput, or else the top of the head. The examiner may find the pain on pressure very severe at the top of the head, and soon after it will have left this place to exist at the occiput, the eye, or at any other region.

When the neuralgia is seated in the first or ophthalmic branch, the painful point is at the supra-orbital foramen, and the pain darts to the forehead, the eyebrow, and eyeball, often being accompanied with a profuse secretion of tears. When this pain is confined to the frontal ramifications of the ophthalmic branch, it has been termed "brow ague," or "clavus hystericus."—When it is seated in the second or superior maxillary branch, the pain point is at the infra-orbital foramen, from whence it shoots to the upper lip, the upper teeth and gums, the posterior nares, and palate, with a tingling or twitching of the cheek and the lower eyelid.—When it is seated in the third or inferior maxillary branch, the pain darts to the temple, to the lower teeth and gums, to the lower lip, and to the chin, being often attended with a more or less profuse discharge of saliva.

The acute form of facial neuralgia, that is, during its commencing periods of attack, say for the first thirty days, is always more severe than the chronic form which occurs subsequently; and the disease is more refractory in its chronic stage than in its acute. Not unfrequently the affection disappears when a cutaneous erup-

tion presents itself, or an obstinate cough, a diarrhea, a vaginal inflammation, severe vomitings, repeated syncope, vertigo, etc.

Facial neuralgia may be determined from *toothache* by the location of the pain in a carious tooth, the pain on percussing the tooth, and by the tooth appearing to be longer to the patient than usual when the teeth are brought in contact with each other; there will also be an engorgement of the gums with redness, ascertained only by an attentive examination, and which swelling may increase and terminate by abscess. Whenever the pain is accompanied or followed by a marked swelling of the gum, even in the absence of any visible decay of the tooth, we may affirm that it is due to dental caries; and whenever a tooth is painful to the touch or to percussion, when it seems longer than usual to the patient, and when there exists no morbid sensibility in the other teeth, no caries being visible, we may likewise diagnose that such tooth is carious. An exception to this exists in those cases where the teeth are not decayed, become loose, from obliteration of the alveolar processes and shrinking of the gums, as with old persons, also become painful, and ultimately fall out without being decayed. In some instances, the neuralgia finally determines dental caries. Removal of the teeth has sometimes cured pains resembling neuralgia; while, at other times, persons have lost tooth after tooth by extraction, without any relief whatever, the neuralgia persisting, or even coming on with redoubled violence. And however excusable the physician may be in these cases of difficult diagnosis, he should never venture upon a removal of a tooth until he has carefully examined the case in every respect, and can not, consistently with the symptoms thus closely considered, believe the neuralgic pain to be due to any other cause than caries of such tooth.

The neuralgia may be determined from *disease of the eye-structure*, in which there is almost always more or less derangement of vision, intolerance of light, and more or less constitutional disturbance. From *organic cerebral diseases* by the presence of paralysis in these affections; at first it may be difficult to discriminate between the neuralgia and the brain maladies, but after a time, if the brain be affected paralysis will manifest itself, as, cessation of the nasal mucus secretion and difficulty in blowing the nose, cessation of the flow of tears on the affected side, loss of hearing, immobility of the eye, strabismus, emaciation, delirium, coma. In such cases the neuralgia is only a symptom of the organic lesion of the brain. From *inflammation of the maxillary sinus*, or antrum of Highmore, by the pains starting from the molar sinus and shooting into the head and neighboring parts,

being accompanied with more or less fever, and usually swelling at the part affected, though this may sometimes be wanting.

2. *Neuralgia of the Scalp and Cervical Neuralgia.* The pain is sometimes located in the scalp, at other times in the posterior cervical region, and the nervous branches are so intermixed that it is impossible to designate the neuralgia according to the branch affected. The posterior cervical plexus, especially the large branch, of the second cervical pair, which passes over the occiput and extends to the top of the head, as well as certain branches of the anterior cervical plexus, as the superficial cervical branch, the auricular branch, and the mastoid branch, are all susceptible of neuralgia. The occipital portion of the scalp receives filaments from the posterior cervical plexus; the lateral and auricular portions receives them from the anterior cervical; and the anterior portion from the supra-orbital nerve; and all these branches or filaments are extended to the vertex.

The pain generally occupies but one side, often having a fixed location, limited to a small portion of tissue, being frequently termed "clavus hystericus," or, when it occupies a greater extent, "ovum hystericum." It is often seated at the top of the head, but it may occupy any part of the scalp; when it is located in the occiput, it forms the variety named "cervical neuralgia," and is usually confined to one side of the head, extending to the mastoid region, the back of the head, along the side of the neck, frequently as far as the shoulder, and then it may be complicated with cramps or contractions of the muscles of the neck. Sometimes the pain may originate in the occiput, and gradually remove so as to become fixed in some other region, as, the temple, the face, the teeth, etc. The pains are extremely severe, and are variously described, seeming to some as if the head were being opened, or a tearing, lacerating pain to others, while others again have sharp rattling noises in the head which they fancy must be heard at a distance. Pressure, during the paroxysm, increases the severity of the pain; during the interval, the sensibility of the scalp diminishes, and pressure only produces a dull soreness or tenderness.

In some cases no pain on pressure is produced either during the paroxysm or the intervals, probably, from not being able to detect the correct focal point. The spontaneous pains may also alternate with those of gastralgia, facial, intercostal, or lumbar neuralgia, or with palpitation of the heart. These pains are often so severe as to compel the patient to cry out, to produce a kind of delirium of action and speech, a disposition to commit suicide, and even the hairs may be seen to have raised. This erection of the hair is

frequently permanent; in some cases, the hair on the affected side of the head falls out, or becomes gray; the patient often experiences an annoying sensation of constantly falling.

When the top of the head is affected, a degree of heat above that of the surrounding parts may often be discovered; and some patients experience such a degree of icy coldness, not appreciable by the examiner, that they will cover their head, but without causing any warmth. The temporal arteries are usually very prominent, swollen, and pulsate strongly, during the paroxysms.

In eleven cases, the pain was fixed four times in the scalp, four times at the top of the head, in a space about the size of a silver dollar; once at the parietal, and of the same extent as the preceding, once at the occiput, and once, throughout the whole scalp, on one side. The pain darted into the neighboring parts seven times; three times to the face, four times to the side of the neck, twice around the ear, twice it suddenly changed sides; once it seemed to pass from one side of the head to the other, and twice it was attended with a spasmodic condition of the muscles of the neck.

Persons affected with these varieties of neuralgia are very liable to relapses; menstruation, especially when the flow is abundant, appears to be an exciting cause among females. When the disease is confined to one side, to the supra-orbital and temporal regions, the pain being one of weight and tension, instead of acute and lancinating, not increased by pressure, but, on the contrary, somewhat relieved, aggravated however by noises or by a jarring of the system, with severe nausea and vomiting, it is termed *hemicrania* or *migraine*. It usually continues for twenty-four hours, or, in severe cases, longer; obstinately resists treatment; terminates by a complete restoration to the usual health, without being thought of during the interval; and may be renewed from time to time without any appreciable cause, or, from some impropriety in diet, labor, exposure, etc., or from depressing moral emotions, etc. This may, perhaps, be a neuralgia of the encephalon itself, or of its membranes. If the brain be diseased, the symptoms of such disease will be observed during the intervals. *Rheumatism of the scalp* occupies both sides of the head; the pain is persistent, and dull, increased by pressure, or motion of the muscles affected, and becomes much relieved upon the application of warmth, which is not the case with *hemicrania*.

3. *Neuralgia of the Brachial Plexus*, which includes the Scapular, Brachial, and Cervico-brachial neuralgia of writers. As with the other kinds of neuralgia the spontaneous pain in the present form may vary in intensity and duration, usually being more acute in

the earlier periods of the disease, and diminishing as the malady continues. The pain on pressure does not always accompany the spontaneous pain; thus we may have the most severe violent spontaneous pain, and, after a very attentive examination, be unable to detect any point painful on pressure; and this pressure may be made upon the exact points to which the patients refer their sufferings. This, however, is the exception; as a general rule, we will develop a very acute pain by pressure, at the time of the paroxysm and, sometimes, pressure upon the focal points during the intervals, will not only occasion pain, but will bring on the neuralgic paroxysm. Hence, the pressure should not be repeated unnecessarily. Sometimes, during the examination, while holding the arm in one hand, and making pressure around the shoulder with the other, the patient will cry out with pain, which we may attribute to the pressure, but which is due solely to a convulsive spasm with painful contraction, determined by a movement which we have given to the arm. This form of pain is often constant, and remains when all other pain has disappeared, so that the least movement of the arm is not only painful, but may bring on a crisis of spontaneous pain. From this cause, we often observe patients keeping themselves in a state of immobility, not daring to make the least motion of the arm, for fear of provoking a paroxysm; and this may be carried to such a point that the patient fears to speak, or turn the head, and yet, notwithstanding all these precautions, an involuntary twitch will occasion a paroxysm. Generally any movement is painful, but in some certain cases pain will ensue from only one or two movements, especially those of abduction. These pains may also appear and disappear without any attributable cause, so that while at one period the patient may move his arm in any direction without pain, an instant afterward the slightest movement is impossible on account of the pain produced; and these pains from motion may exist when there is no pain whatever from pressure. This spasmodic muscular contraction with pain is a phenomenon which may be explained by the nature of the plexus, composed of muscular as well as sensitive fibers; these fibers are isolated from each other from their origin to their termination, yet, notwithstanding this isolation, there exists between the two kinds of fibers so close an association, that when one suffers the other may become convulsed,—for this last condition is not always present. Both the nerves of sensibility and mobility may be affected simultaneously, or, one of these systems alone may be involved.

When the pains are very severe, a muscular paralysis may be

the result; the irritation, by modifying the substance of the nerves, may destroy their irritability, or produce an exhaustion of the nervous force. In luxation of the shoulder, the wresting of the circumflex nerve frequently produces a loss of irritability resulting in paralysis of the muscles of the shoulder, the deltoid in particular. The paralysis, unlike that due to cerebral lesion, will gradually disappear.

The brachial plexus has a number of branches divided into collateral and terminal. The collateral are composed of three groups which the plexus furnishes,—1. Above the clavicle; 2. on a line with the clavicle; 3. in the armpit; they are distributed to the whole of the shoulder, to the supra-scapular region, to the anterior, lateral, and posterior thoracic regions, as well as to the sub-scapular region. The terminal branches are known under the names of internal cutaneous brachial and its accessories, musculo-cutaneous, median, radial, and cubital or ulnar, which are distributed throughout the thoracic limb, and which give to the limb, the same as the collaterals to the shoulder, sensation and motion. As each branch of the plexus may be affected separately, the seat of the pain will vary in each particular instance, and if, following the example of some writers, we would designate the neuralgia according to its exact location, the divisions would be innumerable. It appears, therefore, better to bring them together to a common type, under the name of neuralgia of the brachial plexus, or brachial neuralgia, and then to form three grand subdivisions based upon the three principal regions to which this plexus sends its ramifications, and which we will name the cervical, the scapulo-thoracic, and the humero-palmar. There may be instances where the pain occupies these three regions at the same time, but generally only one or the other, or even a small portion of but one of them. After having occupied a large surface, it may concentrate upon a particular point, and remain there for a long time.

The cervical form is the least frequent of any; it rarely exists alone, or rather, when it exists alone it does not form the neuralgia we are now considering. When it is accompanied with pain on motion, the patients have their heads inclined toward the affected side, which gives them a peculiar aspect.

The scapulo-thoracic form is the most frequent among them; the principal seat of the pain is at the anterior part of the articulation, on a line with the trunk of the plexus; from this point it radiates to the top of the shoulder, likewise frequently to the pectoral region of the affected side, as well as to the supra-scapular and scapular regions, and still more frequently to the scapulo-

vertebral groove or gutter. This latter variety is almost always accompanied with pain on pressure; the collateral branches are therefore affected, especially the posterior thoracic, the supra, and sub-scapular branches, the circumflex nerve, and the anterior pectoral or thoracic branches, without naming the trunk of the plexus, which is very often painful upon pressure.

The humero-palmar form presents the most numerous varieties of location. The pain may be seated in the armpit, and from thence extend along the arm, even to the fingers, especially to the ring and little fingers; or, it may exist only at the internal part of the fore-arm and in the index finger; or, it may commence at the bend of the elbow and extend to the fingers. The internal-cutaneous brachial, the musculo-cutaneous, the antibrachial portion of the median, and the palmar and digital portion of the cubital, are the branches more frequently affected; the radial nerve is less frequently attacked.

It is rare to observe either the spontaneous pain, or that caused by pressure, extend in the direction and following the distribution of these nervous branches; on the contrary, they are more frequently observed to occupy a very limited region, as the top of the shoulder, the lateral part of the thorax, the bend of the arm, the elbow, the internal part of the arm, the fingers, etc. But it must be observed, that in facial neuralgia and in the one under consideration, the conditions are not absolutely the same; in neuralgia of the fifth pair, it is a question wholly of a nerve of sensation, while the brachial plexus is, at the same time, sensitive and motor. The principal seat of the paralysis which sometimes complicates this neuralgia, is the deltoid muscle; that of the contraction or stiffness, is the muscles of the axilla and of the fore-arm.

The pains are generally worse at night; the patient is very apt to be wakeful, and, sometimes, when the paroxysm is very violent, he will be delirious temporarily; eating may sometimes be prevented on account of the pains; and, frequently, there is an abundant perspiration. Sometimes, the disease consists in a constant uneasiness of the affected shoulder, accompanied with moderate pains, which vary according to circumstances.

Neuralgia of the brachial plexus may be determined from *scapulalgia*, or which would be better termed *scapulitis*, by observing that this last is an inflammatory condition of the shoulder and contiguous parts, and is accompanied with a throbbing pain, which darts into the neighboring parts, constant, not progressing by jerks, and increasing or diminishing with slowness. There is pain on pressure, but it is more general than in neuralgia, also heat of

the affected part, and a constantly appreciable febrile reaction. Any movements give rise to pain, and at the termination of the acute stage, there frequently exists a stiffness of the muscles, and there is apt to be tenderness in the part during damp or rainy weather. There is also a pain coinciding with acute or chronic pleurisy, which may be confounded with neuralgia, but which is more of a rheumatic character; this pain may be seated at the anterior part of the articulation, and in the muscles of the posterior part of the shoulder as well as of the corresponding vertebral gutter,—it is increased by pressure on the affected parts, by great respiratory movements, and by very extended movements of the arm. The pain is continuous, and never assumes the rapid shootings of neuralgia.

4. *Neuralgia of the Lumbar* and Sacral Plexuses*, or Lumbar and

* *Pains of the Loins.* Dr. Oke, of Southampton, makes the following very just statements: "Perhaps there is no symptom more commonly met with in practice than pain in the loins, which is usually and at once attributed to bile, gravel, or rheumatism; but as it may be also derived from other causes left out in a hasty decision, I shall enumerate them, and endeavor to point out the symptoms by which each may be distinguished. . . . In order to arrive at its true cause, we must endeavor to ascertain what function is principally involved, which will at once lead us to it.

"If the loin pain be *rheumatic*, it (the soreness) will be increased by pressure, and by the slightest action of the affected muscles. There will probably be also rheumatism in other parts of the body, the system will not evince much disorder, the urine will be high colored and deposit a sediment of urates. (In neuralgia, pressure over the origin of the nerves which are distributed to the loins, will increase the pains, rendering them much more severe. Besides, there may also co-exist neuralgia in other parts of the system.)

"If the loin pain be derived from the *hepatic function* irregularly performed, the pain will shoot upward along the splanchnic nerves to the scapulæ; the alvine evacuations will be either deficient in, or exuberant with, bile, or show a morbid quality of that secretion; the urine will have a bilious tinge; there may be congestion of the hemorrhoidal veins, and the spirits will be depressed.

"If the pain arises from disturbed *duodenal function*, three or four hours after a meal the pain will be aggravated, shooting through toward the right side of the abdomen, and remaining until the food has passed into the jejunum; dyspeptic symptoms will prevail, and sometimes there will be painful pustules or boils breaking out about the face.

"If the pain arise from the *kidneys*, it will shoot down the course of the spermatic nerves toward the round ligament in the female, and toward the testis in the male, which will often be retracted by the action of the spermatic nerves upon the cremaster muscle. There will be more or less irritation communicated to the mucous membrane of the bladder; in which case the urine will deposit mucous, calculous matter, blood, pus, or albumen, according to the nature of the case; or it may be otherwise morbid in its constitution.

"If the pain be from the *uterus*, then it will be more in the back, and will arise

Sacral neuralgia, embraces those neuralgic affections which are seated in the whole or in part only of the lumbar and sacral nerves, whether of the anterior or posterior branches of these nerves, of the superficial or cutaneous branches, or of the deep-seated plexus and the visceral branches. They include the ilio-sciotal neuralgia, sciatic neuralgia, crural neuralgia, neuralgia of the neck and body of the uterus, spermatic neuralgia or of the nervous filaments of the spermatic cord, lumbo-abdominal neuralgia, neuralgia of the urino-genital organs, and of the anus, etc., of writers.

either from disordered function, or disease of that organ. In the first case, the pain will be more of a neuralgic character, will return in forcing paroxysms extending around the hips and hypogastric region, will frequently be attended with hysteria, as well as with increased menstrual discharge. In the second case, from disease of the uterus, the pain will be *constant* and severe, extending along the anterior crural nerve half way down the thighs. There will be a thin, offensive discharge from the vagina, and the countenance will be wan and sallow, exhibiting the wear and tear of organic lesion.

"If the pain be from the *colon*, there will be constipation, and inflation in the course of the bowel, or the fecal discharges will be of small diameter, or there will be soreness of the intestine under pressure, especially at its ascending or descending portions, accompanied by mucus, or shreds of lymph in the form of boiled vermicelli, among the excretions.

"If the pain be from *arterial dilatation*, an abnormal pulsation of the vessel involved—the aorta, for instance—may possibly be detected by auscultation in the incipient stage of the disease, *if such were suspected*; but in a large majority of cases such a cause may reasonably escape the attention of the ablest surgeon, from there being no tangible symptom that might lead him to suspect it; and even after the dilatation has considerably advanced, it may be sufficiently large to press upon and disturb the spermatic nerves, but not large enough to project and pulsate externally, and may, at this stage, be confounded with diseases of the renal function. This can be determined, however, as the aneurismal sac approaches the surface.

"If the loin pain be due to *disease of the spinal column*, the pain will be aggravated by percussing the spinous processes at this part of the spinal column, or by suddenly striking the toes against an uneven surface. There will be involuntary action of the muscles, especially of the flexors of the legs, diminished temperature, abnormal feelings, and more or less loss of power of the lower limbs. Should there be at the same time any unnatural projection of the spinous processes, the disease will be confirmed.

"If the pain be from a *collection of matter upon the psoas muscle, unconnected with spinal disease*, it will be dull, continuous, and deep-seated, extending from the loins down the psoas, or in whatever direction the matter may have taken its course. The pain will be aggravated by flexing the thigh toward the abdomen, and there will be difficulty in walking; moreover, there will be marks of a strumous habit, and more or less symptoms of hectic fever. Should any fluctuating tumor present at the groin, or at any other point where the matter may find its way out of the body, it will be conclusive as to the nature of the case."

In these forms of neuralgia, as in all others, it is important to distinguish between the spontaneous pains and those produced by pressure. The spontaneous pains are felt principally at the period of the paroxysms; they have that particular feature which has been designated under the names of numbness, pricking, cramp, and lancinating, and though very severe, they rarely cause the patient to cry out, but keep up a state of painful irritation, often preventing movements of the body, or compelling the patient to remain in a more or less bent position. Lumbar neuralgia is more frequently seated in the left than in the right side.

In connection with lumbar neuralgia, we frequently observe similar pains seated in other organs, especially facial and intercostal neuralgia, etc. In violent cases the pain extends to the other regions of the dorsal vertebræ, as, between the shoulders, and under one of the scapula, with a feeling of oppression perceptible only to the patient, or accompanied with a manifest acceleration of the respiratory movements, nervous palpitations, nervous vomitings, painful exaltation of the cutaneous sensibility of the loins, of the abdomen, and of the thigh of the affected side, extending to the nerves of the opposite side, which then present a certain number of painful points. In another moment there will be obtuse sensibility of these same parts, a persistence of pains in a very limited region, and which appears to be the commencing point of the neuralgia. The pains referred to above are evidently due to sympathy or to reflex action, and cease with the paroxysm that has given rise to them; in this way may be explained the extraordinary variations of extent and intensity of pains observed in lumbar neuralgia, depending upon whether our examination is made during the paroxysm or during the intervals.

Very frequently sensations of cold and burning heat in the painful parts will occur alternately; a feeling of vacuity, as if there were no longer an abdomen, and which females compare to the feeling experienced immediately after delivery. The pains occur at regular or irregular intervals, and the paroxysm may be preceded by dull pains so that the patient may predict its approaching return.

The pains produced by pressure are especially appreciable when the superficial nerves are affected; but they are much more rare and more difficult to verify in the deep-seated or visceral forms, although they form an important element in the diagnosis. These focal points are numerous and variable; they may be present a number of times with the same individual, follow each other in the course of the disease, or else occupy one single and invariable location.

According to the intensity of the disease, the period of the exam-

ination, and the length of time that has elapsed, the spontaneous pains as well as those produced by pressure, will be found, during the paroxysm, to occupy both sides of the pelvis, the loins, and the abdomen, without our being able to distinguish one region less painful than the other; but the paroxysm once passed, we can not find a single point sensible to pressure, so that, especially in cases of intermittent neuralgia, the patients often feel so well that they delude themselves with the hope that their malady will not return again. This intermittence of the pains is opposed to the idea of a sanguine congestion; but that which confirms the diagnosis is, that after a certain time has passed, we may detect those painful points which we failed to at the commencement. The principal focal points or pain-centers are the following:

The *posterior points* are often to the number of two or three, very limited, seldom complained of as being acute, the patient rarely speaking of them, and which, consequently, we can then only detect by the palpation. In this case, we will observe that pressure will elicit pain in one or several points, along the sides of the lumbar vertebrae, and, sometimes, the corresponding spinous apophyses are painful under pressure; the pain generally occupying a space about the size of a silver dollar.

The *iliac point*, at the center of the iliac crest, is often the only one pointed out by the patient, and is of small extent. It is important to be aware of its existence and to know its origin; otherwise we may be disconcerted by this pain, as we may not know what to attribute it to. It is outside of any uterine connection; it can not be referred to any intestinal malady; it is too low to be connected with the lungs or liver; and we will be unable to refer it to any cause, unless it be to lumbar neuralgia, of the existence of which disease, probably, we should otherwise have had no suspicion.

The *abdominal point*, at the inferior part of the rectus abdominis, has a particular importance in the differential diagnosis; it is generally very limited, and persists with great obstinacy; very often it alone occupies the attention, and we find, only by subsequent examinations, those of the loins and iliac crest which accompany it.

The *inguinal point*, near the inguinal ring, is also one generally pointed out by patients. The *labia majora point*, like the one preceding, is more subject to spontaneous pain than that caused by pressure, and consists of lancinating, smarting, burning pains, a kind of very painful cramp, without the least trace of inflammation. The *supra-pubic point* is more rarely observed; it disappears more rapidly than the others, and more frequently passes beyond the median line, so that it may be felt on both sides, above the pubis.

The *crural point* consists in acute pains which extend along the anterior and internal part of the thigh, which part is sensible to pressure throughout its whole extent, rather than at a limited point. This irradiation is generally temporary, and ceases with the severe paroxysms.

The *aortic point* belongs rather to sacral neuralgia. A very remarkable pain is observed in the epigastric region; upon applying the fingers upon this region we feel a very powerful pulsation, a violent shock caused by the aorta; these pulsations are very annoying to the patient, and are accompanied by an unique sound, heard upon auscultating, seeming like the first or systolic sound of the heart. Upon pressing the aorta so as to have these pulsations under the hand the patient complains of an acute pain, while, as soon as we quit the aorta to press upon the adjacent parts, there is no longer any painful sensation. Not only the trunk of the aorta, but its principal divisions, are the seat of these pains under pressure which are felt even to the loins. Such are the phenomena during the paroxysm; but in the interval the impulse of the aorta is feeble, even difficultly perceptible; the artery having manifestly diminished in volume, and the pain on pressure is nearly null.

The *sacral point* consists in a very acute pain under pressure of one or the other anterior half of the sacrum, and sometimes throughout its whole extent. This painful point may be readily ascertained in certain particular cases, where the abdominal walls are soft and very depressible, either from leanness, or after a recent delivery. However, when we are aware of the possibility of its existence, we may discover it more readily than may be thought. It is accompanied with spontaneous pains in the lumbar vertebræ, and at the posterior part of the thigh, and pain upon pressure over the sacral region, with weakness of the inferior extremities. Elevating the body of the uterus arouses the sufferings, probably because this organ is then made to press against the sacral plexus, the seat of the neuralgia. When palpation through the abdominal walls will not enable us to reach the sacrum, we may discover the sacral point by introducing the finger within the vagina, and pressing, not upon the uterine neck, but upon the sides of the vaginal cul-de-sac; we may thus excite an acute pain on the side affected with neuralgia.

The *uterine point* occupies the neck of the uterus in the absence of any inflammation of this organ. It has been supposed that the pain was exactly confined to that part of the neck situated on the side affected with the neuralgia, but it is difficult to satisfactorily ascertain this. Ordinarily, there is a sluggish condition of the neck, and an acute sensibility to pressure upon one of the sides of

the vaginal cul-de-sac, or else a very decided renewal of the sufferings, when the uterus is elevated by a very slight pressure. The patient complains of acute pain, and if we did not question her closely, we would be led to erroneously believe that the pain was seated in the place where we made the pressure. At the uterine point the pain is spontaneous, deep-seated, with acute and rapid lancinating radiations alternating with a momentary and complete calm; it has no exact seat, but darts in an obscure manner to the groins, the loins, the thighs, and the sacrum, coming on at times by violent paroxysms, which the patient compares to the early pains of labor. At the same time, the uterine neck is exquisitely sensible to the touch, so that the least contact will occasion a paroxysm, and which sensibility may extend throughout the vagina, rendering the introduction of the speculum impossible.

The *anal point* connected with sacral neuralgia, occupies the anus, which becomes so painful to the touch as to prevent the administration of injections; at the same time there are very acute, lancinating, spontaneous pains which will not permit the patient to remain seated, with most painful rectal tenesmus and repeated expulsion of fecal matters. These pains are distinguished by the absence of any appreciable lesion, and by the character of the pains which cease momentarily from time to time, or are replaced by neuralgic pains of the uterus, the vulva, or neighboring parts.

These are the principal points at which pain on pressure may be observed; they may be verified simultaneously or successively with the same individual, so as to constitute a general lumbar neuralgia; or, one region in particular may be the seat of the pains, so as to draw the attention of the physician exclusively to it, the other regions presenting merely some obscure phenomena calculated only to render the diagnosis clearer. For such cases, in order to obtain more exactness, we must not limit ourselves to characterize the disease as lumbar neuralgia, or sacral neuralgia, but should establish true forms, especially when there is reason to fear an error in the diagnosis. Thus considered, lumbar neuralgia may be divided into five forms, the posterior lumbar, the iliac, the abdominal, the supra-pubic, and the inguino-vulvar; sacral neuralgia into three forms, the aortic, the anal, and the uterine. There are some isolated forms, upon which I will now make a few remarks.

The *ilio-scrotal form*, which is characterized by a pressure continuous with spontaneous, lancinating pains through the urethra; pains in urinating which seem to commence at the external inguinal ring and dart into the testicle and the flank, sometimes into the thigh and knee, the chest, and the head, on the affected side

Painful points under pressure are also observed along the tract of the spermatic cord, and on limited portions of the epididymis, with often a swelling of the testicles. During the paroxysm sexual desires are often intense, with frequent pollutions.

The *vesico-urethral*, and the *urethro-vaginal* forms are connected with lumbo-abdominal neuralgia. There are acute and intermittent pains, in the labia majora and labia minora, the meatus urinarius, and the orifice of the vagina, with tenesmus and constipation, and not the least inflammation. This form may exist alone, but it is often complicated with pains in other regions animated by the lumbar nerves; in the more severe or acute stage there is frequent desire to urinate coming on suddenly; urine limpid and voided drop by drop or in small quantity, with a sensation of pain, heat, and smarting in the region of the bladder, and along the canal of the urethra, often extending to the vulva and the rectum, with painful discharges of gas, and also occupying the anterior part of the vagina, which is the seat of agonizing pains, even in the absence of the vesical tenesmus, together with congestion and temporary redness of these regions; paroxysms repeated from one minute to the other, and followed by a respite of several hours; sometimes, an irresistible expulsive sensation like that of labor, and often accompanied with cries; sometimes the patients remark that the sensation is as if everything was being expelled from the abdomen. When these expulsive sensations are renewed, they extend to the anus, with very frequent stools, but no change in the character or the consistence of the feces. These pains may last for several hours, and then completely disappear to return no more; or they may continue several days with alternations.

The disease may be chronic from the start, or it may follow the acute form. The pains are less acute, the patient is tormented with a frequent desire to urinate, and more or less vesical pain, the paroxysm often terminating in vesical pain and repeated discharges of limpid, hot urine.

The *vesico-urethral form* with the male, is less common than the preceding; there are shooting pains, occurring at irregular intervals, sometimes dull, prickling, or tingling, at other times very acute, and which are increased by coition, by prolonged sitting, and by the motions of a carriage, and which are felt in the prostatic region, in the membranous portion of the urethra, but especially and very constantly in the glans; the jet of urine is regular, much more frequent than ordinary, and painful especially toward its termination. There also exists, much more frequently than in the healthy state, a spasm or contraction of the urethra during

catheterism, which renders the introduction of the catheter much more difficult for the operator, and more painful for the patient. Independently of the spasm there exists almost constantly a slight congestion in the neighborhood of the prostate as indicated by the necessity for strongly depressing the pavilion of the instrument, and the tinge of blood almost always observed upon withdrawing it.*

*“There are five pairs of lumbar nerves and six pairs of sacral. The posterior lumbar and sacral are very small, and are distributed to the walls of the loins and of the abdomen, to the scrotum in man, and to the labia majora in women; they may be the seat of the neuralgia.

“The five anterior branches of the lumbar pairs are very large, and anastomose to form the lumbar plexus; this plexus, situated on the sides of the bodies of the lumbar vertebrae between the transverse apophyses and the fasciculi of the psoas muscle, is the seat of the neuralgic pains, either spontaneous, upon pressure, or upon movements of the body. The branches of the lumbar plexus are divided into collateral and terminal; the collateral branches are: 1. The abdominal, designed for the walls of the abdomen, and which we have frequently observed to be affected with spontaneous pains, as well as those upon pressure; (they comprise, the great abdominal branch known under the name of *ilio-scrotal*, because they send a small cutaneous branch to the pubic region; and the small abdominal branch which is equally lost in the skin of the pubis); 2. The inguinal branches, two in number, viz.—the external inguinal branch, designed exclusively for the external and posterior tegumentary regions of the thigh; the internal inguinal branch, which gives off several ramifications;—the internal or scrotal ramification which penetrates the inguinal canal, passes vertically downward, and is distributed to the skin of the scrotum in man, and to the labia majora in woman.

“We must bear this disposition in mind whenever we observe pains in the vulva, the labia majora, and the pubis, with woman, as these frequently occur in lumbar neuralgia; it is the analogue of that which has been described in man under the name of *ilio-scrotal*, except that it is much more frequent; and, whenever we notice such pains, without any appreciable morbid changes in the tissues, we must carefully examine if there do not exist neuralgic phenomena at other points animated by the lumbar nerves.

“The terminal branches of the lumbar plexus are, the obturator nerve, the crural, the large branch of communication of the lumbar with the sacral plexus, or the lumbo-sacral trunk. The obturator nerve is designed exclusively for the external obturator muscle, the three adductors, and the internal rectus. This distribution explains the difficulties which the patients experience in straightening themselves during a severe paroxysm, the obligation to walk bent over, or even to remain immovable in bed, the limbs flexed; and the possibility of walking without pain or even with a complete freedom from it in the intervals between the paroxysms.

“The crural nerve is designed for all the muscles in the anterior region of the thigh, and for the tegument of the same region, as well as for those of the leg and foot, and which will explain why the pains so often extend to the thigh, the knee, and even to the foot, the skin of these regions being of an exquisite sen-

Lumbar and sacral neuralgia may be determined from *morbid organic changes of the spinal marrow*, (especially chronic inflammation of the cord and its membranes), which are very obscure at their commencement, are much more rare than the neuralgiae, are seldom limited to the lumbar region, and give rise to symptoms in the dorsal region, and especially in the cervical region and in the brain. When there are symptoms of even incomplete paralysis of sensation and motion in the inferior extremities, the bladder, and the rectum, with spasmodic movements, there can not be an error in the diagnosis, as these symptoms never exist in lumbar neuralgia. Organic lesions of the cord are often very obscure; at the commencement, there is a sense of fatigue and dull pains in the limbs with periods of acuteness. These pains are distinguished from those of neuralgia by their being commonly on both sides, extending to both inferior limbs, and by being constantly accompanied with rigidity of the muscles of the loins and legs. They are not increased by pressure, as in neuralgia, or else there is a general exaltation of sensibility, especially in the legs. These signs usually suffice. But it may be remarked that if rheumatic affections of the vertebral column have been confounded with

sibility to the touch during the pains, and sometimes in a state of anæsthesia during the interval.

"Of the six anterior branches of the sacral pairs, the first four are joined to the large lumbo-sacral trunk which comes from the lumbar plexus, forming, by their anastomoses, the *sacral plexus*; behind, it is in correspondence with the pyramidal muscle, and in front, with the hypogastric vessels which separate the plexus of the rectum, and of the peritoneum. The last two anterior sacral branches are very delicate, and of little importance. The sacral plexus gives collateral branches, and one terminal branch which is the sciatic nerve.

"The collateral branches are, the visceral branches which are distributed to the rectum and the bladder, in man, and to the vagina and the bladder in woman; there are also numerous branches which communicate with the hypogastric plexus. The other branches are distributed to the muscles of the hypogastrium, the levator ani, the internal obturator, the sphincter ani, the scrotum, to the labia majora in woman, to the muscles of the perineum, and of the penis, to the integument of these organs, to the glutei muscles, the quadratus, the gastrocnemii, to the region of the nates and its integument.

"This disposition thoroughly explains why the pains are so frequent at the anus, the urethra, the bladder, the vulva, the vagina, and the region of the nates, as well as the rectal and vesical tenesmus, so frequently pointed out as symptoms of this form of neuralgia, (*sacral neuralgia*). The hypogastric plexus which overruns the ventral aorta and its divisions with its ramifications, being constituted in part by the great sympathetic, and by the collateral branches of the sacral plexus, we may comprehend how sacral neuralgia may be complicated with aortic pulsations of great intensity, as is frequently observed." (*Neucourt.*)

inflammations of the cord and meninges, at the commencement these neuralgiæ may also occasion mistakes, by presenting accompanying symptoms, such as accelerated respiratory movements, spasmodic movements, palpitation of the heart, general debility, etc.

From *rachidian congestion or hyperæmia, and spinal irritation*, which present such obscure symptoms as to render it difficult to establish the differential diagnosis with lumbar neuralgia. That which is termed spinal irritation may frequently, from want of proper investigation, be only a dorso-intercostal, or a lumbar neuralgia.

These maladies should be investigated with the utmost care, not omitting a very thorough examination in order to determine the points of spontaneous pain, and of that produced by pressure. The presence of congestive symptoms, and the continual pain, soreness, and debility, often increased upon exercise, may lead us to suspect the case not to be a neuralgia. Yet we may have a complication of neuralgia and congestion.—In rachidian congestion we observe very manifest congestive phenomena, which may exist from the commencement of the disease, giving rise to pains throughout the lumbar region, the abdomen, the flanks, and the thighs of both sides, which are aggravated during menstruation, then gradually diminish, remaining on one side, and finally presenting indubitable evidence of neuralgia, the commencing point of which was, probably, in the rachidian congestion. In other cases the neuralgia exists primitively, but it is aggravated by a rachidian congestion, which often gives rise to pain in the lumbo-sacral region, masking the symptoms proper to the neuralgia, which reappear at a later period, when the congestion is dissipated.

From *chronic metritis* in which the inflammation is reflected upon the lumbo-sacral nervous system, occasioning pains in the loins, groins, and thighs, and may give rise to a temporary neuralgia. In lumbar neuralgia the pains are very acute and alternate with a complete calm; the paroxysms occur with regularity in certain cases, and we may determine the exact seat of the points painful on pressure. This differential diagnosis is very important as regards treatment, for should there even be a chronic metritis complicated with lumbar or sacral neuralgia which we have erroneously considered as forming part of the uterine disease, we may not employ means to remove the neuralgia, and thus allow the patient to suffer for a long time; while, if we recognize the true character of this complication, we will employ the proper means for each disease, and will not become disconcerted by the presence of very painful but temporary symptoms, which appear or disappear notwithstanding

the stationary condition of the metritis, and the urgent demands of the patient for their removal. I refer here to the differential diagnosis when both diseases exist simultaneously; but there is still greater danger to avoid, and that is not to mistake a lumbar neuralgia for a chronic metritis.

Lumbar neuralgia is an affection but little known, and to which attention is seldom drawn; the signs by the aid of which we diagnose it with precision demand a careful *manual* examination, as we can not determine it by the patient's description. When she complains of pains in the loins, groins, and abdomen, our attention is usually directed to the uterine organs. We may now find either leucorrhea, or a slight increase in the size of the uterine neck, a little redness, perhaps, some granulations; and we are too often satisfied with these insignificant symptoms, wrongfully considering all the other symptoms as being produced by the supposed metritis.

From *ovaritis*. The ovary has no nervous relation with the abdominal wall, and if we find a limited point, of small extent, painful under pressure, seated at the lower part of the abdominal rectus muscle, the adjacent parts being wholly indolent, without any appreciable tumor, we must refer the pains to a lumbar neuralgia, and discard the idea of an ovaritis. This neuralgic pain is more commonly on the left side.

From *phlegmonous inflammation of the broad ligaments*. In neuralgia the pains are lancinating, intermittent, dart on one side especially, and occupy the exact points painful under pressure. In the phlegmonous inflammation there also exists pain upon pressure in one of the sides of the vaginal cul-de-sac, but at the same time there may be observed a small tumor, in the painful region, independent of the uterus, or, at least a hardness of the tissues which does not exist in the opposite side; the pains are dull, heavy, continuous, and often severe on both sides.

From *anteversion of the uterus*, which is more frequent among women who have given birth to children, and which usually occurs in an upright position from prolonged walking, or the succussions of a carriage, or the exertion of any sudden force while the bladder is empty. The symptoms are better when the patient lies down; and a vaginal examination will detect the anteverted organ. In neuralgia (vesical) the frequent desire to urinate is also present, but it exists independent of lying in bed or in a state of rest; anteversion may occur with any constitution, while neuralgia most commonly attacks pale, chlorotic, nervous, hypochondriacal females, or who are subject to pains in various parts of the body.

The most valuable sign is the normal situation of the uterus in neuralgia, its displacement in anteversion.

From *vaginal cystocele* which may be very easily confounded with vesico-urethral neuralgia, as its most frequent and inconvenient symptom is frequent emission of urine. In order to distinguish these two affections an examination of the genital organs is necessary. In neuralgia the organs are healthy and in their normal situations; in cystocele the patient complains of a swelling which projects between the labia minora. This sign is not sufficient, for in vesical neuralgia, and in simple inflammation of the meatus urinarius, the patients complain of a similar sensation as if a body were about to escape from the parts. The patient must be examined standing, the legs separated, requesting her to bear down a little. If the case be cystocele, we will perceive a reddish, ovoid, soft, elastic tumor, easily reducible, about the size of an almond or of an egg, formed by the prolapsus of the bladder. Sometimes the cystocele is not sufficiently advanced to project externally; we may then find the soft vesico-vaginal wall forming a considerable prominence in the vagina. Cystocele, again, seldom occurs except as a consequence of labor, while neuralgia may exist among virgins and sterile females; the first comes on slowly and is increased by long walks, or active exercise, and the pains are not severe unless the frequent contact of the urine causes an inflammation with swelling around the meatus urinarius; the latter comes on in paroxysms with darting pains.

From *foreign bodies in the bladder and urethra*, as calculi, pins, needles, etc., which may occasion acute pains in urinating, and may be detected by questioning the patient, by the commemorative symptoms, and by an examination with the sound or catheter.

From *cystitis and urethritis* in which there are acute pains in urinating, the same as in neuralgia, but, inflammation is manifested by redness, tumefaction of the urethral canal and of the meatus, with red and turbid urine, and a muco-purulent secretion; the pains are also throbbing, or become acute only when urinating, while in neuralgia they are darting and occur in paroxysms. In the male a urethral neuralgia often occurs after sexual contact, accompanied with a constant titillation, continual formication in the urethral canal, in the seminal vesicles, and in the neck and body of the bladder, and an undulatory rotation of the testicles, with frequent desire to urinate, and a slight sensation of tension and itching the whole length of the canal; this has been termed *dry blennorrhagia*, *dry gonorrhea*, and "extraordinary sensations of the urethral canal, the testicles, and the bladder, following a gonorrhea."

From *vascular tumor of the meatus urinarius*, by an examination of the parts; although the tumor and the neuralgia may co-exist independent of each other.

From *aneurism of the aorta*, by observing that in aneurism we can not feel the diameter of the artery, while in neuralgia this vessel has its normal diameter at all points, and when the impetus of the artery is increased by the neuralgia, the artery is painful under pressure even in its ramifications, to the exclusion of the neighboring parts. The excessive pulsations are not constant, and when we examine the patients at various times, we will ascertain that sometimes there is neither increased impetus nor particular pain under pressure, the aorta itself being difficult to find and to define. Besides which, in neuralgia, there is almost always some other neuralgic point in the loins or in the abdomen. When gas is confined in the arch of the colon, or in the duodenum, and at the same time the aorta, by its energetic action, simulates aneurismal pulsations, it is very difficult to form a correct diagnosis—for we will be very apt to mistake such a condition for aneurism.

As a general rule the *prognosis* of neuralgia is favorable, more especially when it is treated in its earlier periods; but when complicated with some organic lesion it becomes difficult of cure, and may terminate in epilepsy, mania, apoplexy, paralysis, or death.

There are no *pathological appearances* peculiar to neuralgia. In many instances the disease may have continued for many years without any appreciable lesion being observed; or, should there be any, they will be those of some affection complicating, or producing the neuralgia, as tumors, exostosis, ossific deposits, etc., of the brain, or its membranes, or arteries, injection and enlargement of the capillary nerves, thickening of the connecting tissues, etc.; and, in some instances, they are the results of morbid changes effected by the severe sufferings of the patient influencing the circulation in the brain, or in other organs, etc.

The *treatment* of neuralgia, will greatly depend upon its location, its cause, and its complications; general, as well as local means, are usually employed, the former proving the more efficacious in by far the greater number of curable cases.

The treatment of neuralgiæ in general, and which I have found adapted to the greater number of cases, is, to keep the bowels regular, to neutralize gastric acidity, or other digestive derangement, and to administer such tonics as may be indicated; for which purpose the Compound Powder of Rhubarb, or, the Compound Powder of Charcoal may be administered daily, with the addition, to each dose, of such vegetable tonic, or chalybeate, as the case may

require. The skin should be kept in as normal a condition as possible by the means heretofore recommended, not forgetting to make use of the Spirit Vapor Bath, not only during the paroxysm, but also during the intervals when these are lengthy, as often as once every week or two, each time producing free perspiration; the kidneys should also be kept in a proper condition by the use of non-stimulating diuretics. An attention to diet is very important, avoiding everything that will oppress the stomach, or occasion acidity, flatulence, irritation, or constipation, or in any way disagree with the patient. Exposures to cold, damp, sudden changes and malarial districts, must be avoided, as well as depressing causes, either mental or physical, and the body should be kept clad comfortably warm. Moderate exercise in the open air, a pure, dry, warm atmosphere, and temperate living will be found of great efficacy in aiding the cure.

In facial neuralgia a Belladonna Plaster should be applied behind the ear over the mastoid process of the affected side, while at the same time a Belladonna Liniment, or some sedative lotion, should be well rubbed along the course of the affected nerve, and over its tender or painful points; this course should be continued for a reasonable length of time, and then, if no benefit be derived therefrom, a Compound Tar Plaster must be substituted for the Belladonna Plaster behind the ear, and a discharge be kept up from this place for as long a period as the patient can bear,—re-applying the plaster after a short interval should the cure not be permanent. If the neuralgia be in other parts of the system, the Belladonna, or, the Compound Tar Plaster must be placed over those parts of the spinal column that are sore, tender, or painful on pressure, and the sedative lotion be applied along the course of the affected nerve branches and over its painful points.

Internally, one of the following preparations may be administered, according to the scrofulous, rheumatic, or anemic condition of the patient:

1. Take of Sulphate of Quinia one scruple, Elixir of Vitrol one fluidrachm, dissolve the Quinia, and add Tincture of Black Cohosh one fluidounce and a half, Tincture of Aconite Root two fluidrachms. The dose is twenty drops every two hours, in half a fluidounce of water, continuing its use daily until the disease is cured. If, after using this for three or four weeks, no amelioration is effected, it should be omitted; it is especially adapted to rheumatic, malarial, and regularly periodical cases.
2. The Compound Pills of Ferrocyanuret of Iron, in anemic, chlorotic, and periodical cases.
3. In scrofulous cases, the following may be

employed: Take of Bromide of Potassium three drachms, Carbonate of Iron two drachms, Pulverized Digitalis one drachm and a half, Aleoholic Extract of Conium Maculatum two drachms, Simple Syrup, if required, a sufficient quantity; mix thoroughly together, and divide into sixty pills, of which one pill is a dose, to be repeated three or four times daily.

Neuralgia, due to osseous tumors, cerebral or other diseases, as, gout, rheumatism, syphilis, etc., structural lesions of the nerves, uterine, or other irritations, etc., can not, as a general rule, be benefited until such disease, whatever it may be, is first removed by appropriate treatment; and, in all cases of neuralgia, especially when very obstinate, the physician should be as thorough as possible in his investigations, that he may ascertain the existence of any lesion to which the neuralgia may be attributed with a degree of certainty. In a few cases, division of the affected nerve has been followed by permanent relief; but this is the exception and not the rule, as, in the majority of instances the disease returns as severe as ever. And this should be expected, as the cause of the disease rarely exists in the portion of the nerve that has been divided, but is generally due to lesion or derangement of some distant point, perhaps not safely within reach of the surgeon's knife. Neuralgia after amputation is seldom cured; it has, however, been occasionally benefited by acupuncture, and the internal use of sedatives and quinia.

Various other means have at times proved efficacious, and to which I will now refer. During the paroxysm of facial neuralgia, take upon the moistened extremity of the finger, one-third of a grain of finely powdered Hydrochlorate, or Acetate of Morphia, and rub it upon the gums of the affected side for several minutes, the patient inclining his head on that side, so that the gums may be bathed by the saliva for five or ten minutes, and which saliva he eventually swallows. If the pain is relieved, this will do; if not, a second application may be made in the same manner in about four hours after the first application, and, if required, a third may be used in four hours after the second; but it is better not to use the third application, except in cases where the pains are very intense, and have not been relieved. If there is a diminution in the pains, or the patient experiences narcotic symptoms, as, giddiness, faintness, a strong desire to sleep, or nausea, we must on no account repeat the dose. The best effects are obtained from this medication when the neuralgia is seated in the vicinity of the gums and jaw; the results are less effective when the temple, the eye, eyebrow, or ear, are the seat of the pain, in which cases, the

Morphia may be used by hypodermic injections. In many cases, warmth applied, either by means of hot flannels, or, by frictions with the Compound Tincture of Camphor, will be found useful, especially in cases attended with general debility; the warmth acts as a stimulant, giving to the nerve that degree of irritability which it requires.

The physician should be careful about extracting teeth during pregnancy, as facial neuralgia at this period is often due to uterine irritation, and should be relieved by anodyne applications, or leeches.—As worms in the intestinal canal may give rise to neuralgia, or render it obstinate to treatment, the practitioner will do well to bear this in mind, and adopt the necessary measures whenever required.—Dr. Craig, in facial neuralgia, inserts two or three needles near to where the supra-orbital-nerve issues above the eye, and the pain is frequently relieved, as if by magic; he considers the neuralgia, in such cases, as due to a superabundance of nervous fluid in the affected nerve. Dr. McCourty has cured the neuralgia by hypodermic injections of a solution of Strychnia along the course of the facial nerve, between its exit at the stylo-mastoid foramen and its passage to the neck of the condyle of the lower jaw. A few drops to be injected at a time, and repeated every two or three days. He has also cured paralysis of a year's standing, by similar injections over the lower extremity of the spinal cord.

In neuralgia of the scalp, topical applications are difficult to make, and, as a general rule, are of but little efficacy when applied; acupuncture, the needles being kept in their place for an hour at a time; the pomade of Goudret to the top of the head; cold affusions to the top of the head, the patient being in the bath at the time of the affusion; emetics; division of the branches of the occipitalis major, making the incision on both sides down to the bone, and about two inches in length, and then applying caustic from time to time to the wound, so as to keep up a discharge for three or four consecutive weeks; have been found successful in many instances, especially when aided by counter-irritation over the tender parts of the spinal column.

In neuralgia of the lumbar and sacral plexuses, narcotic injections, or the introduction of a small quantity of Opium, or of Extract of Belladonna, into the rectum or vagina, will frequently be found useful, aided by such internal remedies as are indicated by the condition of the patient, as preparations of Iron in anemia or chlorosis; Iodide of Potassium, Guaiacum, Compound Tincture of Colehicum, etc., in cases where a rheumatic principle is sus-

pected; uterine tonics, where uterine irritation is present; urethral injections of Belladonna Extract and Glycerin, where there is urethral neuralgia with vesical tenesmus, etc., and which should be aided by occasional catheterism, or the repeated introduction of bougies into the urethra. In one case of uterine neuralgia, attended with intermittent pains resembling those of labor, the patient being in great agony during the paroxysms, considerable relief was obtained by the use of opium suppositories introduced into the vagina; but finally these ceased to produce any benefit, and the pains continued, occurring regularly every day, remaining for four or five hours each time, and defying all the measures employed; I, therefore, as a dernier resort, ordered leeches applied to the groins, and, to my great surprise, a prompt and permanent relief occurred, the patient not having had an attack since, some two years. Although not certain as regards the matter, still I am disposed to believe that, in this case, the female was in the first month of pregnancy, as there was a flow of blood for some time after I first saw her, and she informed me that a strange-looking substance had passed before I was called to attend her. In another, a case of urethro-vaginal neuralgia, attended with vesical tenesmus, a solution of Nitrate of Silver applied to the vulva and to the walls of the urethra, together with the internal use of Oil of Turpentine, as well as rectal injections composed of a tablespoonful of Oil of Turpentine rubbed up with a sufficient quantity of the Yolk of Egg, repeating it once per day, effected a permanent cure.

In neuralgia of the brachial plexus, sedatives are frequently useful when applied locally, as Belladonna, Opium, Conium, etc., in the form of ointment, liniment, or plaster. Five or six grains of Sulphate of Morphia rubbed up with one ounce of Oil of Sweet Almonds, or of Glycerin, furnishes a very excellent local application. But these are apt to fail with vigorous and plethoric individuals, as well as in cases where there is a tendency to febrile symptoms. In many instances revulsive measures will prove advantageous, as Croton Oil Liniment, Compound Tar Plaster, etc. Shampooing, acupuncture, electro-puncture, and the application of heat, have all been occasionally successful; leeches applied in the neighborhood of the painful part, have likewise been followed with advantageous results. A liniment or ointment of Aconitine or of Veratrine, used as an external application, is very useful in this variety of neuralgia.

The local application of Chloroform has proved promptly efficacious in removing the pain when applied as follows: Moisten a small circular piece of lint, two or three inches in diameter, and

apply it at once to the affected part, then cover this with a concave watch-glass, and keep it in close contact with the skin by means of the open hand applied over the glass. The heat of the hand facilitates the evaporation of the chloroform. A gradually increasing burning sensation will be experienced by the patient, for about five minutes; and in from five to ten minutes considerable irritation will be produced, and all local pain will be removed. This may also be used in rheumatism, and other painful external affections. It reddens the skin, and is followed by desquamation, or a dark brown stain, which disappears after ten or twelve days.

Of late years, hypodermic injections have been employed, and found very valuable; although not always effecting permanent cures, they afford great relief in most cases. They appear to exert a prompt influence in relieving the pain, and are coming into general favor among the profession. I have known daily hypodermic injections of a Solution of Morphia, continued for a month, to effect permanent cures of very obstinate painful affections. The agents that have been used, are the Acetate, Hydrochlorate, or Sulphate of Morphia, in concentrated solution, and a Solution of Sulphate of Atropia, six grains to the fluidounce of Distilled Water; five drops of this solution is equal to one-fifth of a grain of Atropia. From one-half to one grain of one of the Salts of Morphia, in solution, is used (according to the severity of the case and accompanying circumstances) at one injection; or from one-tenth to one-twentieth of a grain of the Atropia solution, repeating the injection as often as required. Should any of the symptoms of poisoning by Opium follow the Morphia injection, combat them by the internal administration of Belladonna; and should any of the symptoms of Belladonna poisoning follow the Atropia injection, they must be overcome by the internal use of Opium. The Atropia is less apt to irritate than the Morphia solution. Hypodermic injections are administered with small graduated syringes, to which are attached hollow needles of steel; a fold of the skin is to be pinched up between the index finger and thumb, so as to hold the part beyond tense, then the needle, held perpendicular to the part, is introduced with a steady, rapid movement into the tense part, after which any desired direction may be given to it; the required amount of fluid having been injected, the needle is withdrawn, and a finger pressed for a short time upon the puncture, in order to prevent the escape of the injected fluid. The effect is usually prompt. If the injection has to be repeated, it will be better to pass it into another adjacent part, because repeated introductions into the same point is apt to induce local inflamma-

tion, nausea, effusion of blood, and abscess. These injections may also be used in cases of wakefulness, delirium, mania, where the stomach is irritable, and when the patient refuses to swallow. They should not be used when cardiac diseases are present, or when neuralgia is due to cancerous affections, etc. I have employed these injections successfully in a number of instances. In neuralgia, the nearer the seat of the pain the injection is made, the more beneficial will be the result. M. Luton, of Rheims, has cured several cases of sciatic, intercostal; and other forms of neuralgia, by hypodermic injections of a more or less concentrated solution of Nitrate of Silver.

Among the internal agents that have been employed in the treatment of neuralgia, the following have been found the most efficacious: 1. Croton Oil in doses to cause a purgative effect, has been found especially useful in facial and sciatic neuralgia. 2. Strychnia has been beneficial in cases where there is no mechanical irritation affecting the nerve at its origin, or along its track, and when there is no cerebral or spinal disease. 3. Valerianate of Zinc, in doses varying from half a grain to two grains, repeated two, three, or four times a day, has proved efficacious in cases not depending upon any organic cause; it has also been of value in epilepsy and satyriasis—and is best administered in pill form. 4. Lartigue's Pills have been recommended; they are composed of Alcoholic Extract of *Sabadilla* thirty-one grains, *Barbadoes Aloes*, pure *Scammony*, each, fifty-five grains; mix thoroughly, and divide into one hundred and ninety-two pills. The dose is two pills every six hours until a purgative effect is produced, and subsequently administering them in doses to keep the bowels moderately purged. 5. Pierlot's Solution of Valerianate of Ammonia, given in doses of three spoonfuls per day. 6. Concentrated Tincture of *Gelseminum* in doses sufficient to produce its peculiar effects. 7. Meglin's Pills, composed of equal parts of Extract of *Hyoscyamus*, Oxide of Zinc, and powdered Valerian; when continued for any length of time they occasion violent and persistent gastric pains. 8. Take of Sulphate of Quinia ten grains, Iron Filings thirty grains, Extract of Valerian fifteen grains; mix, and divide into twenty pills, of which the dose is two pills every two hours. 9. Take of Extract of *Belladonna* fifteen grains, Sulphate of Morphia three grains, Strychnia two grains, Capsicum thirty grains, Sulphate of Zinc fifteen grains, Extract of *Hyoscyamus* a sufficient quantity to form thirty pills; the dose is one pill, to be repeated three times a day. 10. Saturated Tincture of *Arnica* Flowers one ounce and a half, Tincture of *Aconite* three drachms,

Tincture of *Gelsemium* six drachms; mix. I have found this very valuable in some cases, in doses of half a drachm every three hours. 11. Another very excellent preparation is composed of two parts, each, of Extracts of *Valerian* and *Henbane*, and one part, each, of Extract of *Aconite* and Sulphate of *Quinia*, forming the mass into four-grain pills, of which one may be given every three or four hours. 12. Take of finely powdered Hydrochlorate of *Ammonia* two drachms, Ferrocyanuret of *Iron* eight grains, Sulphate of *Quinia* four grains, Camphor two grains; mix thoroughly together, and divide into four powders, of which one is to be administered every one, two, three, or four hours, according to the severity of the attack. At the same time apply the *Belladonna* Plaster, or the Compound Tar Plaster, to the points painful upon pressure; generally, three powders will effect the cure, when the disease is not due to structural lesion. 13. When the neuralgia is due to a gouty or rheumatic principle, the following is considered excellent: Take of Tincture of *Colehicium*, Tincture of *Aconite* Leaves, each, four fluidrachms, Ethereal Tincture of *Belladonna* eight fluidrachms; mix; the dose is from six to ten drops every six or eight hours, in an ounce of Water. 14. Take of *Strychnia* two grains, Phosphoric Acid one fluidounce; mix. To twenty minims of this solution, add Sulphate of *Magnesia* half an ounce, and Peppermint-water six fluid ounces. The dose is from four to eight fluidrachms, two or three times a day. 15. Take of *Formic Ether* two parts, *Formiate* of *Quinia* one part, Distilled Water ninety parts, Syrup of *Codeia* thirty parts; mix. This is said to have proved effectual in very severe and obstinate cases, in doses of a fluidrachm repeated every hour or two. 16. Take of *Potassio-tartrate* of *Iron* two scruples, Wine of *Opium* eighty minims, *Cinnamon Water* eight fluidounces; mix. The dose is one fluid ounce, repeated three times a day.

Among the external applications are the following: 1. Take of *Aconitine* eight grains, Lard, or Oleic Acid one ounce; mix, and rub a small quantity over the affected part with considerable friction, being careful not to apply it over abraded or excoriated parts. 2. Take of *Veratria* one grain, Lard, Glycerin, or Oleic Acid, twelve grains; mix well together. Rub upon the affected parts for fifteen minutes, or until a rash, and a tingling sensation are produced,—repeat the application three or four times a day. 3. Take of Chloroform, Fluid Extract of *Aconite*, Tincture of Camphor, Laudanum, each, equal parts; mix. Rub well over the affected parts, then lay over them a piece of lint moistened with the above, and cover so as to prevent its evaporation. 4. Take of

Extract of Belladonna one drachm, Lard one ounce, mix well together, and add Chloroform two drachms. 5. Take of Croton Oil, Oil of Turpentine, Oil of Sassafras, each, two fluidrachms, Olive Oil two fluidounces; mix. Rub over the painful parts two or three times a day. 6. Take of pure Chloroform four fluidrachms, Cyanide of Potassium two and a half drachms, Lard three ounces, Wax, a sufficient quantity to give consistence. Rub a piece about the size of a pigeon's egg into the scalp, and then cover the head with oil-silk; in facial neuralgia, rub it in over the affected nerve, and repeat it according to circumstances. 7. Apply the vapor of Bisulphuret of Carbon over the tender points. 8. Rub the painful part with Alcohol, and then rub in three or four drops of pure Conia, and cover with oil-silk. 9. In uterine neuralgia, apply the vapor of Carbonic Acid to the uterine neck, for about half a minute or a minute at a time. 10. Take of Formic Ether five fluidrachms, Morphia four grains, Essence of Mint two and a half fluidounces; mix, and rub over the painful points. 11. Take of Hydrocyanic Acid, Glycerin, each, one fluidrachm, Aconitine one grain; mix, and apply over the painful parts with a camel's hair pencil. 12. The continuous galvanic current has proved decidedly beneficial in many instances where the disease is due only to nervous mal-nutrition, not connected with cerebral or spinal disease; in such cases a Pulvermacher chain may be worn. The interrupted current is useless, and frequently aggravates the sufferings of the patient. Neuralgia caused by wounds or organic lesions of nerves or of neighboring parts can not be cured by electricity or galvanism; these agents are only beneficial when the neuralgia is of a rheumatic character, and when there is a mere morbid exaltation of sensibility.

Neuralgia from neuroma requires to have both the tumor and portion of nerve upon which it is seated removed by an operation.—If the neuralgia occur in a cicatrix, it may be due to exposure of a nervous fibril; by exsecting the cicatrix the nerve-twig may be removed also; or, the application of Caustic may, with promotion of subsequent suppuration, effect a similar result!—When an obstinate neuralgia is accompanied with a urinary deposit of oxalate of lime, it will be necessary to administer Nitro-muriatic Acid internally, keeping the bowels regular, using the shower bath, and, if possible, traveling, or changing the residence from city to country and vice versa. In this case, a sedentary life must positively be avoided. If, after the oxalic deposit has been removed, the neuralgia still remains, then adopt the measures heretofore advised.

When neuralgia attacks the throat or larynx, giving rise to what is sometimes termed a *nervous sore throat*, it is accompanied with more or less acute pain along the front part of the neck and throat, which may extend to the sternum, and the fauces frequently have a sense of constriction as if a string were tied around their back part. Sometimes the pain is accompanied with spasm of the muscular fibers, and may be mistaken for spasm of the glottis. As seen by the larynxscope, the larynx is in a perfectly normal condition. Bromide of Ammonium may be employed both locally and internally. Or, Aconitine Ointment may be rubbed along the seat of the pain, and some of the other measures already named for the removal of neuralgia in other parts be adopted.—In all cases of neuralgia, acidity of the stomach, when present, must be corrected by alkalies or absorbents, and tonics.

VERTIGO.

Vertigo, giddiness, or swimming in the head, is a morbid condition characterized by a peculiar sensation, in which it seems to the patient as if everything was turning around him, while himself was turning around at the same time. This sensation may occur either standing or sitting, but more commonly while standing, and usually disappears on lying down. When standing, the patient feels as if he would fall, and grasps or rests upon some near object to prevent it; when the limbs give way, as sometimes occurs, then the patient falls, and at times with considerable violence, as if rudely knocked or pulled down. Loss of consciousness rarely occurs, except in the epileptic vertigo. Vertigo is ordinarily accompanied with paleness of the countenance, a difficulty or even impossibility of speaking and of moving the limbs; sometimes involuntary evacuations of the bladder and rectum take place. The duration of the attack is generally very short, being only a few minutes; if it exists over fifteen minutes, with syncope, the prognosis is very unfavorable, all things else being equal.

Vertigo occurs in various conditions of the system, and may be divided into, 1st, idiopathic or nervous, unaccompanied with any appreciable lesion of the brain; 2d, sympathetic, or that which, without any appreciable lesion of the brain, is due to disease of some other organ, as, dyspepsia, menstrual derangements, etc.; and 3d, symptomatic, or that which is due to a morbid organic change of the brain. From these, two fundamental forms may be established, viz.: nervous vertigo, or that without morbid condition of

the brain; symptomatic vertigo, or with organic lesion, including vertigo from anemia, and that from plethora, in which a particular agent, the blood, determines the vertigo by modifications in its quantity, and in its constituent elements.

1. *Nervous vertigo* is frequently an insignificant condition, which may appear and disappear under the slightest causes, and even without any appreciable cause, at longer or shorter intervals. It may be caused by swinging, the motions of a vessel, see-saw, by being in an elevated situation, by strong moral or physical impressions, close mental application, gastric derangements, confined rooms, use of narcotics, alcoholic or fermented liquors, worms in the intestinal canal, etc. Nervous, hysterical, and hypochondrical persons are especially subject to vertigo; which frequently accompanies facial neuralgia and neuralgia of the scalp. Vertigo frequently precedes an epileptic attack, sometimes for several years previously; in some cases the patient will be stopped in the midst of a sentence for a short time, which sentence he will subsequently finish as if nothing had occurred, being unaware of the interruption. Epileptic vertigo may be suspected when the interruption in conversation occurs, as above referred to, and when it returns, without being due to any appreciable cause, as, the vapor from charcoal, odor from flowers, pregnancy, loss of blood, sudden fright, etc. All irritations of the digestive tube, chronic inflammation, or an acrid, rheumatic, erysipelatous or herpetic principle, may sympathetically irritate the brain and produce nervous vertigo. Dyspnoæic and nervous affections of the bronchia, and lungs, often give rise to vertigo. In nervous vertigo the pulse may remain natural, or be feeble and quick.

2. *Vertigo produced by plethora*, is often accompanied with other symptoms, as dazzlings, tinnitus aurium, deafness, slight derangements of vision, of numerous white or red scintillations, a flushed appearance of the countenance, red and injected eyes, strong and full pulse, rather slow than accelerated, sleep more prolonged and heavy than in health, just the opposite of nervous vertigo. These symptoms are increased by heat, by a stimulating diet, by late rising, by motion, and especially by stooping over, or by the horizontal position which favors the determination of blood in the vessels of the head; they occur among young and vigorous subjects, and more particularly among those disposed to cerebral congestions. In the unfavorable cases there is a heaviness of the head with somnolence and tinnitus aurium, which persist until removed by treatment; in the serious cases, there is momentary embarrassment of speech, cramps and formication, more marked on one side

than the other, a loss of consciousness, or else a sensation of numbness in all the limbs, because the cerebral congestion is general and not limited to one portion of the brain as in hemorrhage. In rare cases, loss of sight, hemiplegia, or even death may occur. Vertigo from plethora may also follow the suppression of a customary flow, as, piles, menstruation, epistaxis, etc., and may be present from pregnancy, residence in confined places, hot baths, exposure to the hot rays of the sun, as well as to intense cold. The immoderate use of fermented drinks is a frequent cause of this vertigo, as well as of meningitis and ramollissement; so likewise is the use of the water of warm mineral springs, whether used as drink, or in baths or douches.

3. *Vertigo produced by anemia*, is accompanied with pale countenance, buzzing or whistling sounds in the ears, emaciation, small and rapid pulse, abnormally slow when the vertigo is accompanied with a partial syncope, slight bloating of the face and other parts of the body, palpitations, shortness of breath, temporary loss of sight, and a blowing, humming, or musical noise in the blood-vessels of the neck, on auscultation. This form of vertigo may occur from profuse hemorrhages, insufficient food, excessive fatigue either of mind or body, from chlorosis, as well as when the general health has become impaired by a chronic disease, scrofula, cancer, tubercles, etc. Sometimes, persons who remain long in the bath, suffer from vertigo, with temporary loss of sight, owing to the diminished flow of blood to the brain, and the consequent want of stimulus to this organ; this, is very apt to occur among persons who thus bathe with empty stomachs. Between nervous and anemic vertigo there is a close correlation, especially in the different cachexias and affections that act simultaneously on the blood and the nerves.

4. *Vertigo produced by an organic cerebral lesion*, is very intense and obstinate, and often precedes, even for several years, the other symptoms of the brain disease; other phenomena may exist simultaneously with the vertigo, as, dazzlings, dimness of vision, objects appearing of a red color, momentary embarrassment of speech, loss of consciousness, partial or complete loss of vision, hearing, or other sense, failure of intellect, and especially of memory, numbness of one side, or cramps, tetanic shock, heaviness of the head, particular awkwardness of the patient in his accustomed work, a cold sensation on one side, formications, permanent contractions, hemiplegia, and all the other symptoms indicative of hemorrhage, ramollissement, or the presence of a tumor compressing the brain. If, at the same time that one or several of these

symptoms are present, there is a more or less persistent vertigo, re-appearing frequently with a person beyond forty years of age, these will be strong indications of the existence of a chronic cerebral lesion. Obstinate vomitings with persistent vertigo, frequently coming on, are often indications of a serious disease of the brain.

The *diagnosis* of vertigo is readily made out by the patient's description; but the great difficulty, in many cases, is to determine its nature or cause. And as the success of the treatment will depend upon the correctness of the diagnosis, the physician should call all his knowledge, tact, and judgment into action during the examination. Nervous vertigo more commonly occurs among the young, and nervous, and is often indicative of some form of epilepsy, especially when it occurs very often; while vertigo from cerebral lesion seldom occurs until after the fortieth year. But, whether the latter form is due to ramollissement, chronic meningitis, cerebral tumors, intra-cranial growths, etc., will in many instances, be a very difficult matter to satisfactorily determine. It must also be recollected, that other diseases than those of the brain may give rise to vertigo, as gastro-intestinal irritations, morbid changes in the coats of the arteries, disease of the heart, lungs, kidneys, or uterus, cancer, gouty diathesis, etc.

The *prognosis* of vertigo should always be given with a degree of reserve. When it occurs occasionally in the young, with no apparent lesion, as in the nervous form, the prognosis is favorable; but when it comes on frequently, with more or less loss of consciousness, and other symptoms of impaired health, and especially when the patient has indulged in masturbation, or venereal excesses, the prognosis is less favorable; it may terminate in epilepsy. Vertigo occurring in advanced or middle age is always to be dreaded, and the more so, if it co-exists with some of the symptoms indicating a lesion of the brain. It is often the case that an elderly person after several attacks of vertigo, will suffer no more from it for two, three, or more years, being apparently cured; but, finally, he will be suddenly attacked with hemiplegia, or with a fatal apoplexy.

The successful *treatment* of vertigo may be summed up in a few words, viz.—Ascertain its cause, and remove that, if possible, by appropriate treatment. If the vertigo is due to plethora, it may be overcome by purgatives, keeping the bowels regular, and the use of diuretics, and sudorifics, aided, in some cases, by revulsives. The diet should be light, and every exciting cause should be avoided, as, any kind of liquor, strong coffee, sedentary occupations, excessive exercise, etc.

If anemia or chlorosis be the cause of the vertigo, it must be

combated by preparations of iron, in some instances conjoined with a preparation of manganese; bitter tonics; and substantial food; keeping the bowels regular daily; taking moderate exercise; keeping the feet warm and dry; and not losing too many hours in sleep.—If it be associated with scrofula, gastro-intestinal derangement, cerebral disease, or any other malady whatever, the proper treatment for such malady must be pursued.

If the vertigo be nervous, or if the morbid conditions above referred to be removed and the vertigo still remains, we must endeavor to ascertain its cause, and if it is accidental, not habitual, and is slight, if it occurs in a person of ordinary health, our means should be rather hygienic than therapeutical. The patient should be removed to a place where he can inspire a pure, fresh air, his clothes should be loosened, and his temples may be bathed with vinegar or cologne, while at the same time the feet may be placed in a stimulating foot-bath, and be vigorously rubbed. In the intervals, he may pursue the course indicated in the preceding paragraph, avoiding every cause which will occasion the least disposition to vertigo. In some instances, antispasmodics may be required, as, Valerian, Castor, Assafetida, Cramp Bark, etc.; in other instances, Belladonna, Quinia, Morphia, etc., will prove useful. When the vertigo is kept up from gastro-intestinal acidity, the Compound Powder of Charcoal, or, Calcined Magnesia will be of service to neutralize the acidity, and, at the same time, keep the bowels regular. Cold water to the head every morning will be serviceable in cases where no cerebral disease exists; in cold weather the water should be tepid. In some cases, counter-irritation by rubefacients, along the whole course of the spinal column, and over the occipital region, will be required; and in some rare cases, suppuration from the nape of the neck, or the cautery to the top of the head may be of service, but I have not yet met with cases where such severe measures were necessary.

Nervous irritability of the brain may exist primarily, but it may also be sympathetic with irritation of another organ, as, of the bowels from worms, of the uterus from menstrual disorder, etc., or, it may result from too great a degree of heat, an active moral impression, insolation, etc.; these causes having been determined in any case, their removal or avoidance will generally be followed by a disappearance of the vertigo.

HEADACHE, OR CEPHALALGIA.

Headache is symptomatic of some functional or organic lesion, often of a serious nature. It may be considered a warning sign, which it is, in all instances without exception, very unwise to neglect; and as the chronicist may be called upon to treat it, a few brief remarks may be made in relation to it.—Headache is common to civilized life, may occur at all ages, and is more serious, as a general rule, when it occurs in advanced life; it may be divided into several varieties according to the causes producing it, the principal of which I will now consider:

1. *Headache from plethora* may exist under two varieties, persistent and occasional; both of these varieties are due to one or more of the various causes inducing a plethoric condition of the system, especially a full and generous diet, and are more frequently met with in spring and summer. In young persons the pain is apt to be severe and rending, and is mostly seated in the temples and brows; while in older persons it is of a heavy throbbing character, and is often referred to the posterior part of the head. The patients usually present a healthy robust appearance. These forms of headache occur more frequently between the ages of thirty and fifty.

The persistent headache is attended with a sense of fullness, sometimes of throbbing, dizziness, and indistinctness of vision, which may continue for several days or weeks. The appetite is good, the bowels disposed to constipation, the urine high colored, the sleep profound but unrefreshing, with sometimes unpleasant dreams or nightmare, and the least exertion determines blood to the head and aggravates some of the symptoms. The pulse may be strong, full, and accelerated slightly, or, it may be strong, full, and oppressed or less frequent than natural, the latter being more common with persons of advanced years; the respiration rather more difficult than usual, with a slight labored action of the heart. If the headache occurs about the menstrual period, or during pregnancy, in addition to the constant aching at the temples and brows, there will be wandering pains and a sense of heaviness in the back and loins increased by motion. Nature sometimes affords relief by the occurrence of an epistaxis, hemorrhoidal flow, or diarrhea. In advanced age, in addition to the above symptoms, there will be flushed face, vascular injection of the eyes, giddiness on stooping, or upon suddenly looking upward, drowsiness after meals, and in some instances, an indistinctness of articulation on waking, which is an unfavorable symptom.

The occasional headache occurs frequently, seldom lasting more than a few hours, is more common among males residing in cities and towns, especially among those of sedentary habits, whose occupations require a stooping position, or who are exposed to impure atmosphere. The pain is very annoying, often occurs in the night or in the morning, and appears to be much influenced by the weather. The stomach is usually acid, weak and irritable, the tongue coated white but rough at its root, the bowels costive, the appetite good but irregular, and the respiration not free.

The *treatment* of these headaches consists in keeping the bowels, skin, and kidneys in as normal a condition as possible. Aperients or mild laxatives, cooling diuretics, and frequent bathings of the surface with considerable friction are about all the therapeutical measures required. In a few rare cases, it may sometimes become necessary to occasionally administer, in the early part of the treatment, an active purgative. A very excellent cooling diuretic is composed of Acetate of Potash fifteen grains, Nitrate of Potash eight grains, Spearmint Water a fluidounce and a half; mix. To be taken at a draught, and repeated twice a day. Syrup may be added to it to render it more palatable. The diet should be moderate and of easy digestion, avoiding acids, fats, and all liquors or stimulating beverages; late suppers especially should be avoided; indulgence in sleep should always be avoided after dinner, substituting in its place some gentle exercise in the open air. Sleep should not exceed nine hours; the bedroom should be airy; the head somewhat elevated on a hard pillow during sleep; and, as soon as awake in the morning, the patient should at once arise, and plunge his face into a basin of cool or tepid water, repeating it two or three times. In warm seasons, a shower-bath of tepid water will prove beneficial, taken every morning. Excesses of all kinds must be avoided. If any accustomed discharges have become suppressed, or, any cutaneous eruptions disappeared, means must be taken to effect their return.

2. *Headache due to congestion* differs from plethoric headache in this respect; in the latter there is an actual excess of healthy blood; in the former, the fault lies in the mechanism of the circulation, in the deficiency of healthy tone in the system, there is an increased quantity of blood in the brain, usually combined with a deterioration of its quality, while, instead of the vessels of the rest of the body being replete with blood, the quantity is often rather diminished. Congestive headache often follows febrile attacks, as well as long-continued enfeebling diseases; it may also be caused by impure air, crowded rooms, narcotics, tight neckcloths, intoxicating

liquors, paroxysms of asthma or hooping-cough, playing on wind instruments, prolonged and intense mental applications, a low posture of the head during sleep, depressing passions, etc.

The pain is dull, heavy, with a sense of weight, and is usually referred to one part of the head. It is apt to be accompanied with some variety of *tiinnitus aurium*, dizziness, dimness of vision, pale, sallow countenance, pale or bluish lips, cold hands and feet, depressed spirits, constipation, sedimentary urine, full and large pulse, easily checked by pressure, or languid, weak, or small pulse, and a disinclination for exertion which aggravates the sufferings and gives rise to palpitation. The patient is usually nervous, or delicate and weakly, though not necessarily thin or slightly made. Sleep is sound, heavy, or snoring, and disturbed. Mental excitement will produce a rush of blood to the head, followed by dull, oppressive pain, and a sense of coldness in the extremities.

Females as well as males are liable to this form of headache, especially those who have exhausted their vitality by excesses, and those of advanced years. If the attack of plethoric or congestive headache be sudden and acute, and attended with giddiness, partial loss of speech, numbness of one of the extremities, it is of a serious nature, and may terminate favorably after an unpleasant and annoying crisis, as vomiting, nausea, great depression, etc., or, it may be followed by apoplexy, paralysis, or insanity.

In the *treatment* of congestive headache, the same hygienic rules should be pursued as advised in the plethoric. Tonics should be administered internally, as the Compound Pills of Valerian, or, Compound Pills of Black Cohosh. In some cases, Citrate of Iron and Strychnia with Extract of Belladonna will be found very beneficial. "The use of Belladonna would seem to be indicated to remove that habitual tendency to congestion of the brain which usually results in apoplexy." (*R. Hughes*.) The feet and hands should be kept warm by wearing woolen gloves and hose, and by friction; and, in winter, the feet should always be warmed before retiring to bed, or, else kept warm when in bed by hot irons, bottles of warm water, etc. If the headaches occur at the "turn of life," uterine tonics will be indicated; or, a mixture of Tincture of Muriate of Iron ten minims, Hydrochloric Acid five minims, Tincture of Blue Cohosh thirty minims, Cinnaomon Water one fluid-ounce, may be taken for a dose, and be repeated twice a day, about an hour after each meal. In a few instances, mild stimulating diuretics may be required, and, rarely, counter-irritation to the nape of the neck.

3. *Headache from derangement of the digestive organs* is a very com-

mon affection, and frequently occurs, although the patient can recall no particular irregularity of diet, and may attribute the headache to the weather, want of exercise, etc. More commonly, however, it can be traced to some particular article of food, to some excess in diet, or to some other cause which may have given rise to disorder in the digestive system. This form of headache occurs chiefly in early and in middle life, becoming less frequent and less severe as age advances, and the irritability of the system becomes diminished. The same cause which, in early life, produces a sick or bilious headache, frequently gives rise, in aged people, to an attack of diarrhea; indeed younger persons, in whom diarrhea is easily produced, are seldom subject to dyspeptic headache.

The pain in the head may be seated in the forehead, temple, or may extend over most of the head; it may be acute, sharp, or darting, but more generally is an annoying sensation of dull weight than of actual pain. There is languor, disinclination to exertion, coldness and numbness of the fingers, slight nausea, tongue coated white, and pale red at its tip and edges, dimness of vision, the eyes aching on reading, the pulse languid and feeble, colored specks floating before the eyes, and inability to concentrate the mind on any subject. Costiveness is usually present. Mental anxiety, sedentary occupations, irregularity in diet, imperfect mastication of food, improper food, eating in haste, or immediately after severe exercise, etc., frequently give rise to this form of headache. An article of food may disagree, may give rise to a headache to-day—when the brain or stomach is unusually excitable—which might have been taken with impunity yesterday, when those organs were less irritable. Mental excitement exercises a powerful influence over the first process of digestion, as well as over the appetite for food; a sudden intelligence or shock frequently destroys the sensation of hunger at once. The brain should be calm for half an hour before and after, as well as during a meal, in all instances. Merchants, stock-brokers, speculators, who are constantly in a state of business hurry and excitement, as well as those who wear out their brains with literary occupations, etc., are especially predisposed to the occurrence of headaches arising from dyspepsia, on very slight errors in diet. The sudden relinquishment of intemperate habits also lays the foundation for indigestion and its headaches; the convert rushing into the other extreme, and positively avoiding the diet that his debilitated frame actually requires. With some persons, whose digestive functions are more or less impaired, one or more particular articles of diet always occasions a diarrhea or a headache.

The *treatment* of this form of headache depends chiefly upon its

cause; if dyspepsia be present, no permanent cure can be had until this malady is removed. However, relief to the headache may frequently be afforded. If the stomach be acid, as evinced by a white coat on the tongue, or if the headache comes on several hours after a meal, a dose of Rhubarb and Magnesia, or of the Compound Powder of Charcoal, to operate upon the bowels, will be followed by relief. If the body of the tongue be pale, some aromatic stimulant may be added to the powder. If the tongue be red, Opium, Belladonna, or some other sedative will be indicated. If the diet, or any of it is of difficult digestion, and the headache comes on within an hour or two after the meal, an emetic should be given. The headache that ensues after inebriation may be removed by two or three doses of the following mixture: Take half a drachm of Supercarbonate of Soda, a fluidrachm of Essence of Peppermint, and a gill of Water; mix for a dose, to be repeated every fifteen minutes. A full dose of Acetate of Ammonia, repeated in half an hour, if necessary, will also relieve the headache from liquor. In other respects, the course laid down under the head of Dyspepsia should be pursued, both as to hygiene and therapeutics.

4. *Sick headache* is of two varieties, and is almost invariably due to indigestible food, or gastro-intestinal acidity, and is peculiar to nervous persons, as well as to those of sedentary habits; habitual constipation, insufficient sleep, intemperance, irregularity of diet, the reaction from any excitement, or sudden and powerful exercise, are among the exciting causes. The first variety is more common in early life, and especially among those who in after years become disposed to apoplexy or other cerebral diseases. It commences with a blurred, obscure, or double vision, which is very annoying, and is accompanied by a sensation of more or less depression; the indistinctness of vision becomes gradually more and more severe, and a slight pain occurs in the forehead and temples, which is at first hardly appreciable, but which becomes very intense with more or less rapidity, often feeling as if the head were being rent apart, and when it reaches its maximum degree of intensity, the confused vision has passed away. As the headache is advancing in severity, nausea sets in, and sometimes vomiting. The countenance is pale, the patient is frequently chilly, and seeks to lie down in a place free from light and noise. Strong pressure upon the temples, pressing them toward each other, affords a temporary relief. Usually, after vomiting, a sleep ensues, from which the patient awakes free from the pain, but with a soreness in the anterior part of the head, which may continue for several days, and which is aggravated by any jarring movements of the head or body. These attacks may occur

every few days, or at much longer intervals; they usually pass off in a few hours, when not treated medicinally, and sometimes the attack will continue for three or four days.

The second variety of sick headache is more common in middle life; the headache generally commences soon after waking in the morning, though it may occur at any period of the day. The pain is at first dull and oppressive, gradually becoming severe and heavy; it is located in the forehead, or one of the temples, usually the left, or over the inner corner of the eyebrow, and, in either case, with a fullness of the corresponding eye. The breath is offensive, the mouth has a clammy, unpleasant taste, the tongue is coated with a yellowish white substance, the hands and feet are cold, the pulse feeble, and frequently severe rigors play along the spinal column. The same as with the first variety, there is a depressing sense of nausea, increased by motion or the erect posture, and the patient seeks darkness and silence. At length vomiting occurs, the contents of the stomach being ejected, or only a thin, acid, acrid, glairy fluid. Sometimes the matters vomited are followed by a yellow, nauseous, and bitter fluid, the bile. In other respects it follows a march similar to the preceding variety.

As the causes of these two varieties are similar, the *treatment* will likewise be the same. If there be acrid or indigestible food in the stomach, an emetic will be the most efficient medication; otherwise, the administration of alkaline solutions will answer. The best preparation that I have ever employed in this difficulty is the following compound: Take of Supercarbonate of Soda half a drachm, Prepared Charcoal a drachm, Camphorated Tincture of Opium a fluidrachm, Water a fluidounce; mix well together and give for a dose. This should be given in the commencement of the attack, repeating the dose every fifteen or twenty minutes, until the headache, or its commencing symptoms, have disappeared. While under its influence the patient should lie quiet, upon his back, in a darkened room, as free as possible from noise or conversation; three or four doses generally checks the further advance of the headache. In some instances, Essence of Peppermint may be substituted for the opiate tincture. If the pain is actually present, in addition to this compound, the head may be bathed with a mixture of Vinegar, Spirits, and Rain Water, equal parts; and a compress moistened with this fluid be fastened over the forehead and temples. The patient should also endeavor to sleep, from which he must be allowed to wake naturally, and after which the headache will be greatly relieved.—In a few cases a purgative will be required to unload the bowels of any offending matters.

To prevent a return of attacks of sick headache, the stomach and nervous system must be restored to a normal condition by the use of tonics, the use of which should be persevered in for many months. A very excellent tonic is composed of Citrate of Iron and Strychnia one drachm, Aletridin one drachm, Powdered Colombo, a sufficient quantity to form a pill mass; divide into sixty pills, of which the dose is one pill, to be taken about an hour after each meal, repeating the dose three times a day. Or, the Compound Pills of Ptelein, or, Compound Pills of Ferrocyanuret of Iron, may be used.

Persons subject to sick headache should keep their bowels regular, avoid all indigestible or acid articles of diet, and keep as free as possible from excessive mental activity or irritability. They should especially avoid the use of those articles, which they have ascertained by experience, render them liable to attacks of sick headache. Acidity of the stomach is the important abnormal condition to be prevented.

5. *Bilious headache* also presents two varieties, one, due to accumulation of bile in the system; the other, to an exuberant secretion of that fluid, either actual or relative. They occur more frequently in summer and autumn, and among persons disposed to hepatic and bilious diseases, especially those of dark complexion and black hair. The first variety is more common in hot climates, especially among those who are irregular or intemperate in their habits. The headache is generally limited to the forehead, eyebrows, and eyelids, and not unfrequently there is a sense of smarting in the eyes and lids. The conjunctiva has more or less of a yellow tinge; the tongue has a brownish or yellowish coat, and may present a cracked appearance at its center. The mouth has a peculiar bitter and nauseous taste in the morning, the appetite is diminished; the nights are restless with annoying dreams; and the patient is apt to be melancholy or depressed in mind.

The second variety, due to an excessive action of the liver, and commonly known as "an overflow of bile," is attended with a throbbing and rending pain in the head, suffused countenance, hot skin, and a bitter, nauseous taste. Objects seem dim, or with a halo around them, and on attempting to read, the letters appear blurred; sometimes the patient feels as if he would fall. Frequently exercise, or a spontaneous vomiting of bile, relieves all these symptoms. Persons who are immoderate in eating and drinking, who eat improper articles, and who are neglectful of the ordinary rules of hygiene, are especially liable to this form.

Bilious headache may be always relieved by either an emetic, or

a purgative; but unless the patient will pay a rigid attention to hygienic measures he must expect its frequent return. Medicines are rarely required, if the patient is attentive to these measures. In cases of long standing, or when associated with some morbid condition of the liver, the treatment must be directed to the functional or organic lesion, in order to effect a permanent cure.

6. *Headache from deficient renal action*, in which the urine is alkaline, of specific gravity 1.015 to 0,130, with deposit of phosphate of lime, and triple phosphates, and a deficiency of urea. The pain is of a dull, heavy, weary kind, affecting the memory and imagination, and disinclining the patient to mental labor, with a sense of debility, and a disposition to drowsiness, with a restless, uneasy sleep. The appetite is good or irregular, the bowels regular, the tongue clean, and the pulse quick, and often feeble.

The *treatment* consists in the administration of Nitro-Muriatic Acid, the use of the spirit-vapor bath every week or two, daily frictions over the surface of the body, and mild tonics; keeping the bowels regular, and using animal food chiefly as diet. In some rare cases, a non-stimulating diuretic may also be required. (*See Treatment of Phosphatic Gravel.*)

7. *Nervous headache* comprises several varieties which are distinct and well-marked in their symptoms; and include also a large number of a mixed character. Nervous headaches are more frequent among females, and males of great nervous susceptibility, and especially those of sedentary habits, or devoted to mental labors. The exciting causes are loud noises, vivid light, impure atmosphere, repulsive odors, venereal excesses, masturbation, worms, improper diet, mental excitements, depression of mind, exposures to cold, dampness, sudden changes, or high winds, loss of sleep, uterine or ovarian irritation, prolonged fasting, exhausting discharges, noxious vapors, etc.

The first variety, or *ordinary nervous headache*, frequently occurs and terminates suddenly; and is exceedingly common among persons of high nervous susceptibility, of vacillating spirits, fickle tempers, and great sensitiveness. The pain is acute and darting, with a sensation of compression and swimming in the head, which are augmented by noises or light. Frequently there is a sense of weight on pressure on the eyeball, which is much relieved when the patient lies with the face turned downward; the pulse is small and feeble, varying with the least excitement, with palpitation of the heart on the least exertion; the bowels are usually constipated; vision dim; memory more or less impaired; the mind dull, peevish, or irritable; despondency; restlessness; a sense of sink-

ing; coldness of hands and feet, often succeeded by heat; eyes sunken; countenance careworn; and more or less debility. The headache commonly comes on in the morning, continues more or less severe throughout the day, and diminishes at night.

The second variety is *hysterical* headache, which is generally due to uterine or ovarian irritation, and may be associated with spinal irritation. It is usually confined to one side of the head, or to a single spot, frequently over one eyebrow, usually the left. When both sides are attacked, the pain is more severe on the left side. The pain is severe, of a shooting kind, darting always from the neck to the temple, and often likened to the sensation of a wedge or nail driven into or pressing on the brain; it is often accompanied with a sensation as of a ball passing from the abdomen and lodging in the throat or head,—from these circumstances it has received the name of “*clavus hystericus*.” Neuralgia of the breast, or of the seventh or eighth intercostal, frequently co-exists. It is frequently associated with anemic headache, and rarely with congestive. Abdominal pains and flatulency are apt to be present. This variety of nervous headache occurs during the menstrual life of the female, between the eighteenth and fortieth year, and may continue, intermittingly, for days, weeks, or months. Excessive exercise, over-dancing, mental shocks or irritations, improper diet, exposures to cold, etc., are exciting causes.—It sometimes occurs in a severe form in both sexes, and is then termed “*brow ague*” or “*hemicrania*.” (See *Facial Neuralgia*.) It occurs chiefly in cold, damp, and marshy districts, is intermittent in its character, and is more frequently met with in middle life.

The third variety is headache from *anemia* or *debility*, and which is due to exhausting discharges, as hemorrhoidal flux, prolonged diarrhea, oversuckling, chlorosis, etc. The pain is generally referred to the top of the head, and is frequently described as resembling a ticking, or the beating of a small hammer on the skull. The pain is not very severe, as a general thing, but is increased by the erect posture, and diminished by the recumbent. The cheeks are pale, as well as the lips, the eyes more or less sunken, with a dark areola around them, vision is impaired, a general sense of debility and languor, dyspnoea, often a sinking pain at the epigastrium, and a craving appetite. Faintness, perspirations, palpitations on exertion, cramps of the legs, depression of spirits, frightful dreams, etc., are apt to be present. Sometimes the headache is sudden, violent, and vertiginous, and attended with *muscæ volitantes*, strange spectral figures, or an apparent loss of vision.

In the *treatment* of nervous headache, but little permanent relief

can be obtained unless the remedies are addressed to the cause; to lessen the pain during an attack is an indication, but it is of minor importance in the treatment. In most instances, the pain can be temporarily relieved by anodynes, combined with stimulants proportioned to the degree of nervous debility. A very excellent preparation for this purpose is a powder composed of Sulphate of Quinia one grain, Piperine two grains, Sulphate of Morphia one-eighth of a grain, Pulverized Assafetida four grains; mix for a dose, and repeat three or four times a day, according to circumstances. The following will also be found useful in cases of nervous exhaustion: Take of Chloroform, Tincture of Ginger, each, half a fluidounce, Aromatic Spirit of Ammonia two fluidrachms; mix. The dose is twenty-five drops in a wineglass of milk, repeated three times a day; it usually relieves in four or five days. The following also, form excellent compounds, both for relieving and permanently curing the headache: 1. Take of Tincture of Aconite two fluidrachms, Tincture of Gelsemium, Tincture of Black Cohosh, each, five fluidrachms; mix. The dose is from twenty to forty drops, three, four, or five times a day, taken in some suitable vehicle. 2. Take of Extract of Aconite half a grain, Extract of Stramonium one-eighth of a grain, Valerianate of Quinia one-fourth of a grain, Extract of Black Cohosh one grain; mix for a pill. The dose is one pill, to be repeated every two or three hours. 3. An infusion of equal parts of Skullcap, Valerian, and Catnip, drank freely, will frequently relieve a severe nervous headache.

But in order to effect permanent cures, a general treatment should be pursued; in the ordinary nervous headache, attention must especially be paid to diet, and the condition of the stomach and bowels, aided by agents to impart tone to the nervous system, and lessen its irritability or susceptibility. For this purpose, the following will be found an efficacious preparation: Take of Ale-tridin, Alcoholic Extract of Black Cohosh, Sulphate of Quinia, Ferrocyanuret of Iron, each, one grain; mix, and divide into two pills, of which one may be taken for a dose, repeating the dose three times a day, for some months. Another very excellent combination is composed of Sulphate of Quinia, Extract of Aconite, each, half a drachm; Extract of Black Cohosh, Extract of Hyoseyamus, each, one drachm; mix, divide into sixty pills, of which give one for a dose, and repeat the dose every three hours. This is especially useful among those of delicate habit of body, and in females laboring under leucorrhea, and uterine derangement. In a few cases, especially those connected with gastric derangement, an occasional emetic will prove of great value, continued until the

foulness of the tongue is permanently removed. Moderate exercise in the open air; sea-bathing, or cold sponging the whole surface of the body, every morning, followed by brisk friction, should also be employed, especially during the warm seasons. Very rarely, counter-irritation will be found useful; as, for instance, a rubefacient to the nape of the neck and behind the ears, or the Croton Oil Liniment. A liniment made of one part of Croton Oil, and eight parts of Paregoric, rubbed upon the parts until pustules appear, leaves no permanent blemish. In many instances of severe headache, in conjunction with the above measures, the feet and legs should be frequently bathed in a warm stimulating alkaline solution, and sinapisms be applied to the soles. Persons subject to any variety of headache, should never wear tight clothing around the neck or upper part of the body. Simple nervous headache is frequently relieved by a full dose of Hoffman's Anodyne. A similar course of treatment will be beneficial in the hysterical form of headache, aided by the proper treatment for the hysteria, according to its cause.

Headache due to debility or exhaustion, requires us in the first instance, to check the enfeebling drain on the system, if still in existence, and then to give tonics to strengthen the whole system, as, the Citrate of Iron and Quinia; the Compound Pills of Ferrocyanuret of Iron; or, the Elixir of Iron and Cinchona. The diet should be very nutritious; a little wine or ale is allowable; the body should be kept properly clad; all physical or mental exertion or excitement must be avoided; and the bowels should be kept regular, without being purged. At the turn of life, where there is considerable flow, with excessive headache, the following will be found exceedingly useful: Take of Tincture of Muriate of Iron one fluidrachm, Hydrochloric Acid half a fluidrachm, Compound Tincture of Cinnamon six fluidrachms, Syrup of Poppy nine fluidrachms, Cinnamon Water fifty-seven fluidrachms; mix. The dose is a tablespoonful every hour or two. It is in this class of cases that the Sulphate of Nickel in half grain or grain doses, repeated three times a day, has been found useful.

Headaches that assume a periodic or intermittent character in their attacks, usually give way to Extract of Belladonna; to a combination of this Extract with Sulphate of Quinia; or to a mixture of Tincture of Gelseminum, Tincture of Black Cohosh, and Sulphate of Quinia.—As headache is frequently kept up by the presence of decayed teeth, a careful examination of these organs should be made in obstinate cases.

8. *Rheumatic headache* is more common among persons who

are disposed to rheumatism, and may be caused by exposure to cold; uncovering the head when perspiring; sitting bareheaded in a current of air; sleeping in a damp bed; as well as other causes that may give rise to rheumatism. The pain is dull and aching, more like intense soreness than actual pain, is generally worse in the evening, and better in the morning, or when warm applications are made. The brow, the back of the head, and the temples, are more ordinarily the parts complained of; sometimes the pain continues in one place; at others it shifts about, and is almost always preceded or accompanied by a sense of coldness over the head and face. There will be soreness and tenderness of the parts complained of, on pressure, which, however, is not restricted to these particular parts. In severe cases if the patient's hair be rubbed sharply in different directions, it will increase his pain considerably. If giddiness, drowsiness, throbbing, flushed face, and injected vessels of the eye, be superadded to the preceding symptoms, it is indicative of an affection of the cerebral meninges, probably from rheumatic metastasis, and the case will demand prompt and energetic treatment.

The *treatment* in this variety of headache will be the same as that described for rheumatism, aided by stimulating liniments over the affected part, as well as dry cupping or other counter-irritating measures to the nape of the neck. If the attack be recent, and arises from exposure, a spirit-vapor bath will be of great service.

9. *Syphilitic headache*, is a disease occasionally met with, especially among those who are of a scrofulous habit, and who have undergone a mercurial course of treatment for the cure of syphilis. The coronal or parietal bones are more generally invaded, as well as the nasal and temporal. The pain is severe, is increased by warmth at night, by stimulating drinks, by exposure to cold and by pressure; in most instances a raised surface can be detected by the finger at the painful spot, wherever it may be located. Sometimes the pain will be of a gnawing character, and when seated at the vertex, a sensation is often experienced as if the head were bursting, or, as if something had fallen from the back part of the head to the front. With this symptom of pain, there may be gnawing pains in the tibia, tenderness of the roof of the nose, sore throat, and copper-colored patches on the body or limbs. The *treatment* will be the same as named for constitutional syphilis, together with compresses over the tender spots, kept constantly moistened with the following preparation: Take of Iodide of Ammonium one drachm, Glycerin, Water, each, one fluidounce; mix. In some

instances, the addition of three fluidrachms of Tincture of Stramonium Seed to the above, will be found to increase its usefulness.

10. *Organic headache*, or that which is due to cerebral disease, is difficult to explain, as the brain itself is perfectly insensible. These headaches are also frequently difficult to detect, as they may give rise to symptoms of gastric disorder, debility, etc., which are of themselves the only causes of many headaches; and should the pain be relieved by treatment, we may be still further deceived, and neglect to attend to the true cause of the headache,—the brain disease. It is of great importance therefore to determine, and at as early a period as possible, the cause of the pain; for headache is frequently the only prominent symptom during the early stages of cerebral disease when this is more yielding to treatment. The pain varies from a fixed uneasiness in the head, not amounting to actual pain, to that of a fixed, deep-seated, very severe, and unchangingly persistent pain, and is increased by mental application, by bodily fatigue, by stimulants, excitements, by stooping, by close or heated rooms, and by cheerful conversation, which usually affords relief in ordinary headaches, becoming laborious and insupportable; and in the more advanced stages the least motion of the head will increase the suffering, or induce vomiting. Nausea or vomiting may appear at any period of the headache, but, unlike the vomiting of sick headache, it is not due to gastric disease or error in diet, and occurs when the pain is most severe without giving any relief. Sometimes the headache is intermittent, or may affect only one side of the head, and be mistaken for brow ague, but may be distinguished from it by the accompanying symptoms of cerebral disease, and by the absence of the causes that may give rise to brow ague. In connection with the headache, there will be brief attacks of unconsciousness, numbness or want of power in the limbs, formication, transient loss of memory, failing of hearing, or of vision, and eventually convulsions, paralysis, or imbecility. In this form of headache, a most careful and minute investigation of the case should be entered into, bearing in mind that cerebral disease may be due to constitutional or hereditary causes, to injuries of the head, to neglected discharges from the nose or ear, etc.

To relieve the headache, cold external applications, counter-irritation, change of air, and anodynes, will be found useful; and, to check the nausea, sedatives may be administered internally, assisted by a rigid attention to diet and regimen; but no permanent cure can be effected, until the cerebral disease, whatever it may be, as tumor, abscess, induration, softening, atrophy, and hyper-

trophy of the brain, abnormal development of bone, etc., is cured by appropriate treatment,—a result by no means of frequent occurrence.

Headache in advanced life is due to no trivial sympathy, but is almost invariably associated with morbid alterations in the structure and the blood-vessels of the brain; at this period of life the energy of the nervous system is diminished, the stomach and bowels are less sensitive, the muscular tissue is no longer renovated with the ceaseless activity of adult life, and thickenings, indurations of, and morbid deposits in blood-vessels and other tissues are very common. The patient complains fretfully of headache, is dull and stupid in the morning, becoming peevish as the day advances, with the head hot, and the tongue dry and brown; questions are often incoherently answered; and sometimes the sufferer being early put to bed, will be found during the night, unconsciously wandering about the bedroom.

High feeding is opposed to longevity, and, with old persons especially, the diet should be curtailed; animal food should be sparingly used; the diet should consist principally of chocolate, cocoa, arrowroot, gruel, jellies, etc., and the body should be kept at a proper degree of warmth both during the night and day. Medicines to relieve the cerebral disease, should be used cautiously, as the "power of resistance to disease" being diminished, no cure can be expected; palliation is all that the physician can do; at the same time keeping the bowels regular by gentle aperients, or by figs, stewed prunes, etc., together with dry cupping to the nape of the neck to overcome severe symptoms, and some gently stimulant and cordial tonic to relieve debility. The less medicines are given to aged persons, the better will it be for them.

Headache, with pain across the eyebrows, and at the root of the nose, with dryness of the nostril, frequent sneezing, occasional giddiness, red and watery eye, may occur from eggs of insects being deposited in the nostril, and lodged in the frontal sinus, where they produce their "grubs." Headache may also be occasioned by lead-poisoning, by worms in the intestines, by certain affections of the eye, ear, heart, kidneys, and other organs, and by drunkenness, and is also peculiar to certain trades and occupations.

CRAMP.

Hypochondria, syncope, hiccough, nightmare, palpitations, etc., are only symptoms of certain functional or organic lesions, which, although generally treated upon separately, will not be considered

here as distinct affections; a removal of the disease giving rise to them, or of which they are an accompanying symptom, will be followed by their disappearance. A few remarks may, however, be made concerning cramp attacking the limbs.

Cramp is a sudden, violent, and very painful spasm or contraction of one or several muscles, particularly of those of the calf or posterior part of the leg; it more commonly manifests itself during the night, often arousing the patient from his sleep. Cramp in the limbs may be due to debility and overaction of the muscles attacked; to an improper position in bed, frequently occurring when the patient overstretches the limb with the toes drawn downward; to direct compression of a principal artery, muscle, or nerve; and to derangement of the digestive organs. It is also symptomatic of spinal or cerebral lesions, which the physician must keep in mind when investigating the causes of frequent and severe attacks of cramp. It may also be due to other causes, as, cholera, etc., not included in the limits of this work. When the cramps are attended with headache, mental debility, formication, numbness of the limbs, etc., a very close examination should be made to ascertain the existence of spinal or cerebral disease; for the complication of cramp with these maladies is an indication of their severity and danger. When the muscles of the superior limbs are attacked, the danger is greater than when the cramp is confined to those of the lower; and the danger is still more imminent when the spasm extends from the superior to the inferior limbs.

Cramp of the lower leg not associated with disease of the brain or spinal cord, may be almost instantaneously relieved by drawing or pressing the superior surface of the foot as closely as possible toward the tibia, and holding it thus until the spasm passes off, which will occur in a few seconds; or, in ordinary cases of cramp in the extremities, a ligature may be placed around the limb above the affected muscles. To prevent the recurrence of the spasms, an attention must be paid to diet and regimen, with gentle exercise of the affected muscles, and daily frictions with the Compound Tincture of Camphor. If derangement of the digestive organs be the cause of the cramp, the appropriate measures must be adopted to overcome such disorder. It has also been recommended to have the bed or mattress upon which the person sleeps form an inclined plane, so that the head may rest twelve inches higher than the feet, and which may be effected by cutting down the lower legs of the bedstead so as to form this inclination.

When the cramp is due to cerebral or spinal lesion, the only means of permanent cure is, the removal of the spinal or brain dis-

ease; though, in such cases, the cramp may often be relieved by the measures above recommended, with frictions, etc.

Mrs. S—, aged twenty-six, of strumous diathesis, after the birth of her first child, became subject to menstrual derangement, with great nervous exhaustion, and cramps in the fingers, toes, arms, and legs. These cramps would sometimes occur daily, and at other times would not appear until after an interval of several days; they were very severe. She labored under more or less constant headache, rigors along the spinal column, irregular appetite, cold hands and feet, occasional formication along the spinal column and the inferior limbs, diarrhea, etc. Viewing the case as one arising from a cerebro-spinal derangement, I placed her upon the following course of treatment, which effected a cure in the course of seven months. Take of Bromide of Potassium one ounce, Water twenty fluidounces, Solution of Perchloride of Iron one and a half fluidounces; mix. The dose was a teaspoonful administered three times a day about one hour and a half previous to each meal. Pustulation by means of Croton Oil Liniment was kept up alternately over the nape of the neck, and one or the other mastoid process; and the following lotion was applied along the spinal column twice every day: Take of Strychnia five grains, Alcoholic Extract of Belladonna one drachm and a half, Camphor half an ounce, Alcohol four fluidounces; mix. The diet was regulated, as well as the bowels; and no other exercise was permitted than that of a passive character. An infusion of High Cranberry Bark, Skullcap, and Sassafras Bark was used as a common drink, several times a day.

CHRONIC DISEASES OF THE CIRCULATORY SYSTEM.

NOTWITHSTANDING the laborious investigations of many eminent physiologists with regard to this class of chronic maladies, there yet remains much to be done, both in the way of diagnosis and treatment. In the acute affections of the heart, as a general rule, an experienced and practiced ear may be able to determine the location and character of the disease with an almost positive certainty; but in chronic maladies of this organ and its appendages, so many various parts may be involved, and such varied morbid changes be effected, that it proves a difficult, if not, in some instances, an impossible thing to diagnose them with any degree of certainty or even of satisfaction. And should we be enabled to positively discriminate the peculiar character of the heart or arterial malady under which a patient is laboring, unfortunately for him or her, we can promise nothing certain as regards treatment, for in this class of chronic diseases therapeutics have proved very unprofitable.

Diseases of the heart and arteries may be located in one or several parts of these organs, and may be complicated with, or be the result of, disease of other organs; either of those adjacent, as, for instance, the pleura, lungs, etc., or of those at a distance, as, the kidneys, brain, etc. And in our investigations of cardiac affections, these phenomena should constantly be borne in mind, so that we may connect facts and circumstances in a proper manner, and thus be enabled to arrive at correct diagnosis, and, as far as possible, efficient treatment.

Among the principal symptoms observed in functional or organic affections of the heart, are the following, viz.:—Slight difficulty of breathing, increased by exercise; more or less pain in the region of the heart; suffocating weight; a short, dry cough, and often spitting of blood on the least exercise; breathing by starts; great anxiety; no expectoration; palpitations; irregular and intermittent pulse, frequent and bounding, and sometimes unequal in the two

wrists, not synchronous; enlargement of the chest immediately over the heart; slight exertions, and sometimes the least excitement produces palpitation; timidity; apprehensions of evil, or of dying; fainting; diminution of strength; chills; rheumatic affections; cardiac epilepsy; heart beats tumultuously and indistinctly; irritable temper; bleedings from the nose and sometimes from the lungs; purple lips; sometimes the heart acts so powerfully that the whole system can be seen to shake; swelling of lower extremities; occasionally a puffy swelling appears suddenly on the face, particularly under the eyes, and after a day or two as suddenly disappears; a distress which the patient can not locate in any particular spot; sometimes the patient can not lie down from the palpitation and suffocative breathing; dropsy of the lower extremities; partial impotency; derangement of the urinary discharge both in quantity and quality; oppression and constriction in the region of the heart; angina pectoris, or pain and constriction in the left side of the chest, with a peculiar numbness and more or less pain in the left arm, particularly on the inside as low as the elbow; the countenance presents a peculiar and haggard appearance. Heart disease is often produced by self-pollution during youth. Very few of the forms of disease to which the heart is subject can be permanently cured, though in many cases much relief may be given by the adoption of proper measures.

Before entering upon a description of the symptoms and treatment of heart affections, I will briefly refer to certain matters connected with auscultation and percussion of this organ, which it is important for the practitioner to be acquainted with. A full and thorough explanation of these matters is not included within the scope of this work; and it can only be obtained from the excellent monographs of Hope, Latham, Stokes, Walshe, Flint, and other writers upon cardiac diseases.

The præcordial region, or region of the heart, is that space upon the walls of the chest that defines the outline of the organ, including its base, apex, and lateral margins. "A line drawn from the inferior margins of the third ribs across the sternum, passes over the pulmonic valves a little to the left of the mesial line, and those of the aorta are behind them, but about half an inch lower down. A vertical line, coinciding with the left margin of the sternum, has about one-third of the heart, consisting of the upper portion of the right ventricle, on the right—and two-thirds, composed of the lower portion of the right ventricle and the whole of the left, on the left. The apex beats between the cartilages of the fifth and sixth left ribs, at a point about two inches

below the nipple, and an inch on its sternal side." (*Hope.*) And any change of this position of the apex is indicative of disease of the heart, or of its surrounding parts. The heart lies obliquely, having its long axis directed from right to left, forward and downward, its base corresponding, in front, to both third costal cartilages, and its apex to the sixth left costal cartilage. Posteriorly, the upper margin of its base is opposite the fourth dorsal vertebræ, and the lower margin opposite the seventh or eighth, being separated from the spine by the aorta and œsophagus.

In a state of health the heart presents certain sounds and impulses, which are normal, and any variation in degree or quality of which indicates a greater less departure from health. These normal sounds of the heart may be detected by auscultation in the præcordial region; it will be ascertained by carefully listening at this region, that for one pulsation of the arteries, the heart gives two successive sounds, with two hardly appreciable intervals of silence between them.

The *first, systolic, or inferior* sound may be heard more distinctly over the apex of the heart, below and rather to the outside of the nipple; it is duller and more prolonged than the second sound, is synchronous with the contraction or systole of the ventricles which expels the blood from the cavities of the heart, or the heart's shock against the ribs, with the pulse at the wrist, and, for the most part, with inspiration.

The *second, diastolic, or superior* sound may be more distinctly heard at the upper part of the cardiac region, above, and a little to the inside of the nipple, near the margin of the sternum; it is clear, sharp, and short, is synchronous with the dilatation or diastole of the ventricles, which admits the entrance of blood into the cavities of the heart, with the recedence of the heart from the ribs, with expiration, and with the interval between the pulsations not being synchronous with the pulse.

The interval between the first and second sounds is called the *first or post-systolic silence*, and that which follows the second sound is termed the *second or post-diastolic silence*. If the whole period from the commencement of one pulsation or entire revolution of the heart to the commencement of the next be divided into ten parts, the average periods of sound and silence will be very nearly as follows: For the first sound four parts, for the first silence one part, for the second sound two parts, and for the second silence three parts. This order of succession is termed the heart's *rhythm*. A precise idea of these sounds can only be obtained by auscultation; they will be found to vary materially at different parts of

the cardiac region, in intensity, duration, pitch, and quality, while the periods of silence can only differ in duration. Some difference will also be perceived from change of position on the part of the patient, from morbid changes in the lungs, hepatic or splenic enlargements, nervous excitement, excessive debility, etc., the heart remaining healthy, or being only functionally affected.

The *impulse* of the heart, is its beat or stroke against the walls of the chest—also termed the apex-beat, the position, extent, force, character, and rhythm of which may be more or less modified by disease, muscular exertion, mental excitement, forced or accelerated respiration, position of the body, obesity, etc. It may be felt by placing the hand upon that portion of the chest corresponding to the apex of the heart, and usually the impulse is visible.

In diseases of the heart and its arteries, the sounds, the rhythm, and the impulse of this organ become more or less altered; in addition to which, adventitious sounds are perceived, and which are called *murmurs*.

The heart-sounds may be increased, as, in functional excitement of the organ, simple dilatation, hypertrophy, etc.; they may be weakened by obesity, softening, fatty degeneration, atrophy, morbid infiltration, etc. The duration of the sounds, or the rhythm of the heart's action may be irregular in various ways; and the distance of the sounds from the auscultator's ear, will be perceptibly increased in cases of fluid or gaseous accumulation in the pericardium, while they will be brought nearer to the ear than natural, by enlargement of the heart, or adhesion of its pericardial surfaces.

The character or quality of the sounds of the heart, as well as of their pitch, may also undergo considerable change. Thus, in a dense hypertrophy with thickening of the valves of the auricles, the first sound becomes dull, muffled, and toneless; but when the walls of the ventricles are thin, and the valves natural, it becomes more or less clear, flapping or clicking, with raised pitch; however, if the ventricular walls are in a state of eccentric hypertrophy, with thickening of the valves, the sound is of a changing nature. Both the first and second sounds will be found to undergo modifications depending upon the character of the malady, and the particular parts influenced by it. In certain cases one sound may be single and the other double; or both may be double; or the same sound may be double at one locality and single at another, etc.

The sound and impulse of the heart, should generally be taken together. A clearer sound leads to the suspicion of a thinned heart, but if it be accompanied with a weaker impulse, we are

certain that the walls of the organ are attenuated. A stronger impulse may lead us to suspect hypertrophy, but the suspicion becomes certainty if at the same time there is a diminished sound. If both sound and impulse are increased, there is probably no hypertrophy, but a more forcible action of the heart from excess of nervous energy, and vice versa. If both the sounds and impulse are detected beyond the præcordial region, they generally indicate dilatation of one of the ventricles; if the sound predominates over the impulse there is attenuation with the dilatation, or rather less than a proportionate increase of muscular substance; if the impulse predominate over the sound, there is hypertrophy with the dilatation, or rather more than a proportionate increase of its muscular substance.

The intervals of silence are also modified by disease; if the arterial walls are feebly elastic, or if the first sound is disproportionately shortened, the first silence is lengthened. If the mitral orifice is constricted, the second silence is lengthened. And so with other causes. And all these various modifications, together with their indications, should be thoroughly understood, and carefully investigated by the practitioner.

The position and bulk of the heart may be ascertained by percussion; but this is a difficult matter, requiring a considerable degree of experience before it can be reliably accomplished. Yet, in order to establish a satisfactory diagnosis of certain maladies of the heart, it is of essential importance that percussion be brought in as one of the methods of investigation.

It must always be borne in mind that respiration exerts a certain influence upon the heart, effecting a change in its position with regard to the walls of the chest; thus, during a full inspiration, the heart's action diminishes in rapidity, its impulse in the interval between the fifth and sixth ribs is hardly if at all observable, while, at the same time, the heart's-sounds become greatly lessened, and the dullness of the superior margin of the præcordial region changes its location to the extent of two or three inches. In many cases, however, the impulse may be detected downward and inward, from three to nine lines to the left of the center of the ensiform cartilage, at which point percussion will elicit dullness, while at the normal point of impulse between the fifth and sixth ribs, it will elicit quite a clear sound.

In a full expiration the heart's action is rather increased in rapidity, its impulse is very sensibly felt, and apparently occupies a greater extent, while the præcordial dullness of the superior margin is decidedly augmented, the systolic sound being frequently much

louder. And although these changes may not always be present, yet during an examination by auscultation and percussion, it must always be present to the mind of the examiner, that they do most commonly occur.

The adventitious sounds or murmurs are divided into endocardial, and exocardial, or pericardial; they are entirely different from the ordinary sounds of the heart, and are the results of certain morbid changes within or on the surface of the heart.

Endocardial, intracardiac, or valvular murmurs, are usually more inward and deeper, and further from the ear, and are characterized by a blowing sound, which may vary from that so soft as to resemble the passage of the gentlest wind, to that of a very harsh character, or cooing, whistling, etc., and the pitch of the murmur may be high or low-toned. Various terms have been applied to this murmur, according to its peculiarity; thus, it has been termed a bellow's sound, (*bruit de soufflet*); sound like sawing, (*bruit de scie*); sound like rasping, (*bruit de râpe*); musical sound, (*bruit musical* or *sifflement modulé*); sound like filing, (*bruit de lime à bois*), etc. But notwithstanding these variations in the quality of the endocardial murmur, they are of but little importance, as they have only one common significance, namely, morbid conditions interfering with the integrity of the valves. The endocardial murmur may occur at any period of the heart's rhythm, it may be pre-systolic, systolic, post-systolic, pre-diastolic, diastolic, or post-diastolic, and it may occur during the sounds and silences of the heart in various ways. It may take the place of the heart's natural sounds, and be heard in their stead. It is regularly or irregularly intermittent, and when once developed is habitually persistent. It is essentially indicative of something wrong inside of the heart; but to determine the nature of this something, we must note the time in the heart's beat or rhythm when it occurs, the space within which it is chiefly heard, the direction in which it is conveyed, and the preceding and accompanying symptoms of the constitution generally. But it must be remembered, that even in the most acute cases, endocardial murmur is not a certain evidence of disease.

Endocardial murmurs have been divided into Organic and Inorganic. *Organic endocardial murmurs* are generally associated with valvular abnormalities, as, constriction of the valvular orifices, thickening, hardening, calcification, or roughness of the valves, excrescences, etc., which are determined by the quality, duration, pitch, intensity, and period of time of the murmur.

Inorganic endocardial murmurs have been subdivided into 1, *hæmic*, depending upon some abnormal condition of the blood, (spanæmic),

as in chlorosis, profuse hemorrhage, exhausting diseases, sexual excesses, inanition, etc., or from the formation of coagula within the heart, interfering with the regular progress of the blood current; and, 2, *dynamic*, depending upon some abnormal action of the heart, as, from violent excitement of this organ, dynamic changes interfering with the closure of its valves, etc.

The *bruit de diable*, noise like a humming top, is a continuous hum or cooing like that which reaches the ear from the hollow of a sea-shell when applied close to it, also called the "venous hum." This is an inorganic murmur due to an impoverished condition of the blood, though it has occasionally been heard among young healthy persons. It is more readily detected over the internal jugular vein, and will cease when the vein is firmly pressed upon by the finger, returning when the pressure is removed.

Dr. Chambers recommends as by far the "best extant means of distinguishing single pericardial and valvular murmurs—sounds precisely the same in their effect upon the ear, and occurring often at the same period of the cardiac movements, and, therefore, undistinguishable unless particular manipulation be used. The plan is—first, fit the stethoscope firmly and steadily on the place where the murmur is loudest, and get impressed on the auditory nerve clearly the special character of the murmur; then, keeping the instrument still closely applied to the chest in the same position, remove your head very gradually, and try to gain a point at which you can hear the normal heart-sounds without the murmur. If you *can* do this, the murmur is pericardial. If you can not, but the murmur is heard as far off as the heart-sounds, it is endocardial. In all cases where the disease is endocardial only, or pericardial only, the knowledge thus obtained may be safely acted upon."

Exocardial, extracardiac, pericardial, or friction murmurs are usually more outward, nearer to the surface, and closer to the ear, and are characterized by a rubbing, or to-and-fro sound, presenting, however, various modifications. The principal modifications are: 1. The *friction, or attrition murmurs*, which may resemble a to-and-fro rubbing murmur, a grating, scratching, creaking, squeaking, grazing, clicking, or prolonged whistling sound. *Bruit de frottement*, a rubbing or friction sound; *bruit de cuir neuf* or *bruit de craquement*, a sound resembling the creaking of new leather; *bruit de raclement*, a scraping sound, etc. 2. *Continuous murmurs*, resembling a rumbling or squashy churning sound. 3. *Clicking murmurs*; and, 4, murmurs caused by the *bending or crumpling of layers of tough exudation matter*. These murmurs are generally indicative of some morbid condition of the pericardium.

The pericardial murmur does not take the place of the natural sounds of the heart, nor is it heard in their stead; it may accompany either the systole, or the diastole, or both together; it may vary in pitch, intensity, duration, extent, and regularity, becomes increased in sharpness when the patient bends forward; is changeable in seat and intensity, and is sometimes attended with friction-fremitus or a sensation of vibration or friction when the finger is applied over the region where the murmur is heard. It is sometimes so soft as to be with difficulty distinguished from the endocardial murmur, requiring the closest attention to determine its character, or even to detect it. Both the pericardial and the endocardial murmur may co-exist when pericarditis is accompanied by endocarditis.

These are, in brief, the physical signs met with in investigations of the heart, both in its normal and abnormal conditions, and without a thorough understanding of them in all their various combinations, modifications, etc., it will be impossible for any one to treat cardiac diseases with any degree of certainty or satisfaction. The medical man must make himself intimately versed in them.

A few general rules may be now referred to, as regards diagnosis of the maladies under consideration:

1. The most formidable organic diseases of the heart are those of the valves. Though valvular disease of an extensive character may exist for several years without compromising health to a serious extent, and without abridging the usual term of human existence. As a general rule, if there be no cardiac murmurs, there is no valvular lesion, and vice versa.

2. Disease of the aortic valves is frequently associated with hypertrophy, and, in aortic regurgitation, also with dilatation. Cerebral symptoms are also more common and urgent.

3. Disease of the mitral valves is mostly associated with dilatation. Pulmonary symptoms are also more common and urgent.

4. Adhesions of the pericardium are more generally associated with dilatation.

5. Atheroma of the aorta and renal disease, are frequently associated with simple hypertrophy.

6. In aortic regurgitation the pulse is generally "jerking," or sudden and sharp.

7. In mitral insufficiency, the pulse will be soft or irregular, and there will be a bellows murmur with the first sound, heard loudest over the apex.

8. A friction murmur, synchronous with the heart's movements, indicates pericardial lesion; in rare cases it is wanting. Tumult-

uous action of the heart is frequently an indication of pericarditis.

9. Aortic insufficiency is indicated by a bellows murmur with the second sound, heard loudest at the base.

10. "A murmur with the second sound, loudest at the apex, is very rare, but when present it indicates—1st, Aortic disease, the murmur being prolonged downward to the apex; or 2d, Roughened auricular surface of the mitral valves; or, 3d, Mitral obstruction, which is almost always associated with insufficiency, when the murmur is double, or occupies the period of both cardiac sounds."

11. "A murmur with the first sound, loudest at the base, and propagated in the direction of the large arteries, is more common. It may depend—1st, On an altered condition of the blood, as in anæmia; or, 2d, On dilatation or disease of the aorta itself; or 3d, On stricture of the aortic orifice, or disease of the aortic valves; in which case there is almost always insufficiency also, and then the murmur is double, or occupies the period of both sounds. It may occasionally depend on roughness of the ventricular surface of the mitral valves, and on coagulated exudation attached to the internal surface of the heart."

12. "Hypertrophy of the heart may exist independently of valvular disease, but this is very rare. In most cases it is the left ventricle which is affected, and in connection with mitral or aortic disease. In the former case the hypertrophy is uniform with rounding of the apex; in the latter, there is dilated hypertrophy, with elongation of the apex." "When the heart is enlarged, and still more when it is adherent, there is diminished motion of all the ribs on the left side, with the exception usually of the second and third. If there be pericarditis, the motion is still more interfered with, and the motion of the abdomen just below the xiphoid cartilage is also much affected, being in all cases lessened, and, in some extreme cases, quite interrupted. While the motion of the center of the abdomen is diminished, that of the abdominal walls at each side is usually not affected." (*Sibson*.)

13. Disease of the heart is sometimes present with chorea, especially when this is due to a rheumatic affection.

14. General anasarca, with no change in the blood, nor albumen in the urine, is nearly always indicative of disease of the heart or large vessels, even when there are no important cardiac symptoms present.

15. *Fremissement cataire*, cardiac, or *valvular thrill*, is a strong thrill or purring tremor, resembling the purring sound of a cat, which

may both be heard and felt by the hand when applied over the spot where it occurs; this thrill is always accompanied by a bellows murmur, and is very distinct in insufficiency of the mitral valve with dilated hypertrophy of the left ventricle, its seat being below and within the nipple, and also in constriction of the aortic orifice coupled with the same kind and location of hypertrophy, its seat being at the aortic base. It is more frequently met with in the former condition than in the latter. It may also be observed in chlorosis, becoming less distinct as the blood improves. Stokes considers this thrill to be the pulse of aortic regurgitation on a large scale, and indicative of regurgitation into the ventricles of the heart, into a large or a dilated artery, or into an aneurismal sac.

This tremor may be felt most distinctly when the flat hand is laid over the part of the præcordium corresponding to the point of the heart's impulse. "If it be due to narrowing of the left auriculo-ventricular opening, it will be perceived at the period corresponding to the heart's diastole; if it occurs when the impulse is feeble, the heart broad, (as indicated by increased lateral dullness on percussion), and the second sound increased, it is due to the same narrowing, as above stated; if it coincides with an increased impulse, an hypertrophied left ventricle, (as indicated by a tremulous impulse and increased dullness, in the longitudinal direction, on percussion), and with absence of the second sound of the heart, it may be considered as due to imperfection of the aortic valves; if both contracted left auriculo-ventricular opening and imperfect aortic valves are present, the tremor accompanies the diastole, the sound of which is increased and audible in the pulmonary artery, and absent in the aorta and carotid arteries, and the heart is enlarged in its longitudinal and transverse directions." (*Jaksch*.)

In examining a patient suspected of laboring under some cardiac lesion, the practitioner will first ascertain the history of the case, its past and present symptoms as noticed by the patient; he will then observe the condition of the face, the eyes, the breathing, the pulse, the palpitations, whether any cough or dropsical swellings are present, and also inquire into the condition of the renal and intestinal excretions. This effected, he will then inspect the cardiac region, its form, whether prominent or depressed; the condition of its integuments, whether the præcordial interspaces are of the same width, and lie on the same plane as their fellows on the opposite side, and whether the soft parts on both sides present the same characters; and, the impulse of the heart, whether visible or not, at what point visible, its character and force.

He will next proceed to examine by palpation or application of

the hand, to determine the position, character, extent, force abruptness, sharpness, shortness, etc., of the heart's impulse; the movements of the præcordial ribs and interspaces, whether they are widely separated or bulged outwardly, or whether they are narrowed; and the condition of the *vocal vibration* or *fremitus*, (a peculiar thrilling sensation communicated to the fingers when applied to the chest of a person while he is speaking); whether this be augmented, diminished, or annulled; also whether there be present any fremissement cataire, or pericardial tactile friction fremitus, or a rubbing or friction sensation or sound of short duration, and generally movable from one part of the cardiac region to another.

In the next place, the practitioner will percuss the cardiac region for the purpose of determining the size of the heart, and whether hypertrophy, dilatation, or pericardial effusion, etc., is present. The next and last means of exploration will be auscultation, by which the sounds and murmurs of the heart are distinguished, their character, location, pitch, combination, etc.

Acute carditis, endocarditis, and pericarditis, may exist separately or together, and if not permanently removed, may result in a chronic form of the isolated or conjoined affections. The terminations of these inflammations into a chronic form, are generally associated with certain morbid changes and conditions of the heart and its arteries, as, effusion, hypertrophy, etc.; therefore, instead of treating upon chronic pericarditis, chronic carditis, etc., as distinct diseases, I will only refer to those chronic conditions of the organs under consideration which may be the result of some previous acute inflammatory action, or which may exist and gradually progress, independent of any previous acute attack. Indeed, as a general rule, these chronic affections are only clinically known by their effects upon the valves and orifices of the heart, hypertrophy, hydropericarditis, etc.

ORGANIC DISEASES OF THE HEART.

PERICARDIAL ADHESION

Also termed Chronic Pericarditis, may be the result of the acute form of the disease, or may exist independently of it. The *symptoms* will be found to vary considerably; with some patients there will be merely a pain in the cardiac region, which may be constant

or occur at regular or irregular intervals; with others there will be shortness of breath and easily excited palpitation; again, all these symptoms may be present, together with many others, as, uneasiness upon lying on the left side, sense of suffocation at different times, startings in sleep, apprehensions of dying, etc. The pain will vary in intensity, in some instances being hardly noticed, while in others, especially when the result of a rheumatic attack, it will be very annoying, and be frequently shifting about. The pulse is generally frequent, and may be regular or irregular. Pressure upon the epigastrium in the direction of the pericardium, sometimes occasions a sense of soreness. In some instances the affection presents no prominent symptoms, and is with difficulty detected by auscultation, palpation, and percussion, if detected at all.—Pericardial adhesion is more usually associated with some abnormal condition of the heart, as, atrophy or hypertrophy, but it may occasionally exist with the heart in a perfectly natural condition.

It is by no means an easy matter to form a positive *diagnosis* of pericardial adhesion from the physical signs, more especially when it has been in existence for some time, as these signs vary according to the closeness of the adhesions, and to the presence or absence of adhesions of the pleura, and they are also present with other morbid conditions of the heart and its vessels. Auscultation may detect clicking sounds, or friction sounds from loose adhesions, or a slight single rub occurring with the systole, and a kind of abrupt, undulatory, double-jogging or tumbling motion of the heart. The heart's impulse may be felt in its natural location, or slightly above it, and a depression of the præcordial region may be felt in the neighborhood of the fifth and seventh left cartilages, or above, at the base of the organ. Dullness on percussion may also be found just above the third left cartilage. Yet these signs can not be positively relied upon as indicative of pericardial adhesion, as they may be present in other lesions of the heart, or may be more or less wholly wanting.

It is rarely the case that a chronic adhesion of the pericardium results in death, not unless it co-exists with effusion, hypertrophy, or atrophy, etc., in which instances the *pathological appearances* will be the same as named under Dropsy of the Pericardium, Hypertrophy of the Heart, etc. The pericardium may present a degree of redness, with or without a change in its consistence, transparency, and thickness; opaque, white, tough patches may be observed upon various parts of it, the result of exudation, and which may be removed, leaving a healthy surface beneath; or, a white,

obscurely-defined patch may be perceived upon its anterior part, which is not removable, and which is probably due to continued friction.

The *treatment* will consist of measures to lessen excitement, and promote absorption. For the former, an attention to the skin, bowels, and kidneys are especially required, together with a diet of nutritious but non-stimulating food used moderately and at regular intervals; the use of *Veratrum*, *Gelsemium*, *Digitalis*, *Cactus*, or *Aconite*, to quiet any tumultuous action of the heart; an avoidance of sudden and powerful mental and physical actions; and, when the irritation is considerable, counter-irritation over the cardiac region, and anodyne applications, as, plaster of *Aconite*, *Belladonna*, etc.

For the latter measure, above named, *Iodide of Ammonium*, *Bromide of Ammonium*, etc., may be administered internally, and may also be employed locally, in the form of wash or ointment, over the affected region. Or, a plaster may be employed, consisting of *Extract of Belladonna* one drachm, *Iodide of Ammonium*, moistened with *Alcohol*, fifteen grains, *Iodine* five grains; mix and form a plaster. If rheumatism be present, or the patient be subject to this affection, the internal remedies recommended for its treatment must be employed.

If the pericardial disease be attended with, or be due to tubercular disease, which may be suspected, when tubercular symptoms are present in the lungs or other organs, or where the patient has been long exposed to the most powerful exciting causes of tubercular cachexia, the remedies advised for such tuberculous or scrofulous conditions must be administered, together with counter-irritants to the chest, saline diuretics, tonics, good, nutritious food, and a speedy removal from the influence of depressing causes.

HYDROPERICARDIUM.

Dropsy of the Pericardium may be the result of acute pericarditis, especially when this is consequent on acute rheumatism, may occur as a phenomenon of general dropsy, or it may be due to pressure, or morbid conditions of the large blood-vessels of the heart. In aged persons hydropericardium is apt to be the result of ossification of the aorta.

When due to a previous acute attack, the *symptoms* will vary considerably; the pulse may be small, frequent, irregular, intermitting, and weak; syncope; obscure palpitations, jugular veins distended, countenance bloated, and more or less of a livid color, extremities cold, a feeling of weight and oppression in the præcor-

dial region, and more or less of an inability to respire freely in the horizontal posture. The symptoms depending principally upon the particular cause of the dropsy, or upon the accompanying morbid conditions of the heart and its appendages. Sudden startings during sleep are common. Dropsy, cough, and dyspnœa may be present, but in a very mild degree; the adjacent structures may become variously displaced, as, the margins of the lungs, the left lung itself, the liver, central tendon of the diaphragm, etc., which may be pushed upward, or downward, etc., according to the degree of fluid effused. Generally the patient can rest more easily by lying on the side affected.

Inspection will discover more prominence of the præcordial region, and a fullness or widening of its intercostal spaces, with more or less external œdema in this situation; the impulse will be undulating, and will be felt upward and somewhat outward, about the fourth intercostal space, behind and slightly external to the nipple. These symptoms, as well as those detected by auscultation, are not constant, and will vary according to the degree of fluid present. Perhaps the most valuable sign is that resulting from percussion, which detects an increased præcordial dullness of a triangular shape, the base below, and the apex above; the base usually corresponding to the sixth or seventh ribs, and the apex of the triangle reaching to some point between the second left cartilage and an inch above the clavicle. The right margin of the triangle may frequently be detected by the vocal fremitus, which will be strong over the condensed tissue, and feeble or null over the fluid.

Auscultation will detect any irregularity in the force of the impulse, and in the rhythm of the heart; friction-sound may, or may not be heard at the base of the heart. The sounds of the heart will be feeble, muffled, and distant at its apex, but will increase in loudness as the stethoscope is carried upward; the second sound will be full and loud at the summit of the sternum, while the first sound will be much more marked at this point than directly over the ventricles. When the apex lies behind a thick body of fluid, if the hand be applied while we are auscultating, the heart's impulse will be found to lag a little behind the systolic sound.

When the hydropericardium forms part of a general dropsy, the presence of the latter, its cause, together with the signs of pericardial effusion, must all be taken into consideration, in order to avoid an incorrect diagnosis; the general symptoms will be in accordance with the disease occasioning the local dropsy.

When the hydropericardium is due to impeded or disordered

circulation, the result of chronic organic changes of the heart, lungs, etc., the fluid accumulates slowly and no inflammatory symptoms are present. In many cases, the patients will be debilitated, and of a lymphatic or leucophlegmatic diathesis. It is only when there is a considerable amount of fluid present that the patient will experience any decidedly marked symptoms, as a weight in the cardiac region, pain in the back and loins, sense of oppression, sometimes dry cough, inability to active exercise, palpitations, cold and œdematous extremities, depression of spirits, lividity of the lips, an inability to remain in the horizontal position, and a scanty, high-colored, and turbid urine. These symptoms vary considerably with different patients, and with many the only symptoms complained of will be the sense of weight and oppression. The pulse may be regular or irregular.

The physical signs will be very similar to those named above when the disease is due to an acute attack, with the exception that there will be no prominence of the præcordial region, no sound of friction, and the triangular præcordial dullness will have its apex considerably below the point named above.

The *diagnosis* of hydropericardium is by no means an easy matter, and especially when it is complicated with disease of the valves, etc.; besides which, a pleuritic effusion, which almost always accompanies the pericardial effusion, may cause a displacement of the heart, and may also obscure the symptoms very much. Consequently, we must take into account all the symptoms present, as, derangement of the heart's action, and of the pulse, weight and oppression in the cardiac region, the impulse of the heart, as if transmitted through a fluid, the triangular præcordial dullness on percussion, the sounds from auscultation, the absence of the fluctuation in hydrothorax, palpitations, syncope, cold and œdematous extremities, previous history of the case, etc.

The *prognosis* is unfavorable; but less so in the first variety described. Yet cures are sometimes effected, and remedial measures should always be thoroughly and perseveringly pursued.

Post-mortem examination reveals various conditions according to the cause of the effusion and its complications. In the first-named variety there will be evidences of inflammatory action present, as, thickening of the pericardium, deposits of lymph, and albuminous flakes in the fluid; and the fluid may be serous and turbid; albuminous; almost purulent, or even bloody. And several lesions may also be detected, as, of the heart or its valves, of the pleura, and of the lungs and bronchial tubes.—In the second variety there will be no injection of the pericardium, as in the preceding case; and this

covering will be found opaque, somewhat thickened, and perhaps softened; sometimes it will be quite white. The fluid will be colorless, yellowish, brownish, or greenish, and mostly limpid; but sometimes turbid. The surrounding organs will likewise, as a general rule, be found in an abnormal condition.—The appearances in the third variety will resemble those of the two preceding forms, depending, however, upon the particular cause of the effusion, and the character and location of the morbid conditions.

The *treatment* of hydropericardium, after all inflammatory symptoms have been subdued, will consist principally of alterative tonics and counter-irritants; hydragogues and diuretics will be found of no service, except to remove accompanying dropsy of the extremities or other parts; and in those cases due to organic changes in the lungs, heart, or great vessels, their employment will more generally be followed by serious consequences, from the great depression they occasion;—hence they should be used, if at all, with great care, and only in those instances where the strength and general condition of the patient will permit. Dry cupping, or wet cupping over the region of the heart will often be found advantageous as an external means; or, the application of a Compound Tar Plaster, keeping up a discharge for a long time. The strength of the patient must be kept up by tonics and nutritious diet; and Iodide of Potassium, Iodide of Ammonium, or Chloride of Gold and Sodium be administered internally, or, such other remedies as the accompanying lesions or primary disease may require. The Chloride of Gold and Soda, in particular, will greatly promote absorption and relieve the effusion, and also act as a diuretic. In connection with these means, a persevering and prolonged use of the Compound Infusion of Parsley will be found a most valuable auxiliary, especially in those cases where there is much debility, paleness, or anemia. An attention to the general hygiene of the patient, adapting it to his particular condition will also be a necessary part of the treatment.

Paracentesis pericardii or tapping the pericardium, has been proposed, and in a few cases has been performed successfully, while in others it has afforded temporary relief. M. Aran relates a case in which he performed pericardial paracentesis twice within twelve days, twenty-eight ounces of fluid escaping from the first operation, and forty-nine ounces from the second. After each operation he injected an ioduretted solution into the sac; the result was successful. It must be recollected, however, that if the disease occasioning the effusion of the fluid be not removed, there will, after a longer or shorter time, be a renewed accumulation of fluid. The cases in which this operation will prove more successful, will, it seems to me,

be those in which the effusion is the result of inflammatory action. If the operation be performed, great care should be taken to prevent the introduction of the external air.

At this place I will make a few brief remarks relative to *Cardiac Dropsy*, or dropsy resulting from a disease of the heart. Medical writers have not positively determined the particular cardiac affections which occasion dropsy, though it is well known that patients who have suffered for years from valvular affections, hypertrophy, etc., have ultimately died without dropsy having occurred, or, if it did, it was only during the last weeks of life. Dropsy may occur, however, from hypertrophy, dilatation of the right side with or without a tricuspid regurgitation, or any other cardiac disease which interferes with the flow of the venous blood; the dropsy not depending so much upon the extent of heart disease present, as upon the degree of venous congestion it produces, and the impoverished condition of the blood.

The first observable symptom of anasarca due to a cardiac lesion is a swelling of the feet and ankles, pitting upon pressure; the swelling increases, and gradually ascends upward. Indeed, a dropsical swelling beginning in the ankles is considered a very important indication of heart disease. Sometimes the swelling will be first noticed about the eyelids, which is as important in its indication as when it commences in the inferior extremities. The swelling in the feet is usually worse in the evening and better in the morning; that in the face is worse in the morning, and better at night. The infiltration is at first confined to the subcutaneous cellular tissue, but eventually increases and extends into the peritoneal and pleural cavities, the pericardium, and indeed into every serous cavity of the body.

In connection with the dropsical effusion, certain symptoms of heart disease may also be detected; thus, cough and dyspnoea may have preceded the dropsy, or may accompany it; there may be irregular movements of the heart; the heart may be felt and heard to beat beyond the præcordial limits; its impulse may be unnatural; there may be fluttering palpitations, distended jugular veins, a dusky skin, and livid lips and extremities. Or, the patient may have at some time previously suffered from an attack of acute rheumatism, which may have occasioned some cardiac lesion to be ascertained by a thorough investigation. In aged persons, a series of symptoms will be present indicative of organic changes in the heart and great vessels.—The heart disease may or may not be associated

with some affection of the kidneys; and this latter malady may of itself give rise to what is termed *renal dropsy*.

In the *treatment* of cardiac dropsy it must be borne in mind that, unless the heart disease giving rise to the dropsy be cured, no permanency of cure can be expected; for after its disappearance under treatment, the effusion may appear again and again. Besides, any serious lesion of other organs, as, the liver, kidneys, lungs, etc., anemia, plethora, or constitutional taint, which may co-exist with the cardiac dropsy, will render this disease less amenable to treatment.

The principal remedies for the removal of the dropsy, are diuretics and hydragogues, such as are hereafter named under the treatment of Dropsy; in conjunction with such agents as are calculated to improve the condition of the heart, to repair the impoverished blood of anemia when this is present, to remove any constitutional taint, and to impart strength to the general system. The use of the spirit-vapor bath once or twice a week, according to the strength of the patient, will also be found exceedingly beneficial. When the patient is greatly debilitated, we must be very cautious in the employment of active depletory agents, as, hydragogues, diuretics, and profuse sweating; in such instances the greatest benefit will be derived from the prolonged use of the Compound Infusion of Parsley, made with equal parts of good Holland Gin and Cider, instead of Cider only. Of course, the general hygiene of the patient must not be neglected.

HYPERTROPHY OF THE HEART.

Hypertrophy or Enlargement of the Heart is an increase of the muscular tissue of this organ, more generally occurring in the left ventricle, but also found affecting the right ventricle, as well as the auricles. When the muscular walls of one or more of the heart's cavities are thickened, the cavities remaining of their natural size, it is termed *simple hypertrophy*. If with the thickening of the walls the cavities become diminished in size, it is termed *concentric hypertrophy*, or, *hypertrophy with contraction*, which, together with the previous form, is of rare occurrence. When the walls are thickened, and the cavities become larger than natural, it is termed *eccentric hypertrophy*, or, *hypertrophy with dilatation*. The hypertrophy may be limited to one or two compartments, or it may be general and affect them all. Males are more liable to the disease than females; and it is more commonly met with after the middle period of life, though younger persons, even to childhood, are not wholly exempt from it. Hypertrophy of the heart

is rarely met with alone, dilatation of the cavities, and valvular affections are more generally co-existent with it.

The *cause* of hypertrophy is generally some impediment to the circulation requiring an increased effort of the heart to surmount it, or, an obstruction to the free play of this organ. Dr. Barlow divides these causes into three classes, viz.: 1. Obstruction from changes in the orifices of the heart, or in the course of the circulation. 2. Obstruction arising from changes in the quantity or physical properties of the blood. 3. Deficiency of strength in the parietes of the heart itself.—Among the exciting causes may be named those which act by habitually stimulating the heart, as, excessive use of fermented liquors; exciting moral emotions; violent and prolonged muscular efforts; a sedentary life in conjunction with the habitual use of rich and stimulating diet; intemperance in alcoholic liquors; excessive venery, or masturbation; a rheumatic diathesis with a syphilitic taint; and the irritation of an adherent pericardium. Impediments to the circulation are produced by aortic contraction, or regurgitation; mitral contraction, or regurgitation; which give rise to hypertrophy in the left ventricle and auricle. Tricuspid regurgitation, and narrowing of the pulmonary artery, or any impediments to the circulation in the lungs, exert a similar effect upon the right ventricle and auricle. Prolonged obstructions to the renal capillary circulation, as well as to the general capillary circulation, may also produce the disease under consideration.

The *symptoms* of hypertrophy of the heart are, a sense of oppression, shortness of breath, and palpitation, which occur especially on exertion, or on ascending high ground, stairs, etc.; these symptoms, however, are not so urgent as in some other affections of the heart. The pulse is full, strong, and firm; losing, however, some of its strength and resistance, if dilatation be also present. The face is generally florid, unless dilatation co-exist, when it will be more or less purple or livid, according to the degree of dilatation. Anasarca is not, as a general rule, an accompanying symptom. The pulsations of the carotid arteries may be seen. Headache, vertigo, epistaxis in the young, and apoplexy in the old, are frequent attendants, the latter more especially in advanced stages of the disease, in which secondary morbid changes in the brain are liable to be generated.

In the *diagnosis* of hypertrophy of the left ventricle, we will find a fullness or arching of the præcordial region, with widening of the left costal interspaces from the third to the seventh; this will be more especially observed in advanced cases. The impulse of

the heart raises the hand applied over its apex with an increase of force proportioned to the amount of the disease. The point of the apex-beat, instead of being between the fifth and sixth ribs, is lower down, sometimes as far down as the eighth rib; and may also be carried outward or inward, from changes effected in the position of the heart as a consequence of its enlargement. It may be regular or irregular, depending upon the absence or presence of some other co-existing abnormal condition, slower than natural, and of a heaving character.

The pulse will be strong, jerking, or vibratory, is increased by exercise or mental excitement, and when palpitations are present, it participates in the tumultuous action of the heart. On percussion we find the præcordial dullness to have extended both transversely and longitudinally, losing its triangular form, for one having more of a square outline. Auscultation will detect the systolic sound dull, muffled, prolonged, and the diastolic sound loud but of lower pitch than natural, and of a clanging character. No bellows murmur will be present, unless there be some other morbid condition present.

The physician must not misjudge the condition of the patient merely because the sounds of the heart can be heard over a large extent, even if they be sharp and clear, as this is by no means indicative of cardiac organic disease; it is not uncommon for palpitation to be present, with the sound propagated over the whole chest, and yet no organic disease be present. Hypertrophy lessens the normal sound; thinness of the walls of the heart, gives the sounds clear and shrill; dilatation of the cavities and thinness of the walls, give loud and clear sounds, but if hypertrophy be present instead of thinness, the sounds will be loud, dull, and the first sound slow.

If the hypertrophy be accompanied with dilatation, there will be some variations in these physical signs. The extent of impulse will be much greater, it may be felt as far as the eighth rib, as well as in the back; is not so heaving as in the simple form, but is sharper, and more knocking, or slapping. The force of the impulse may be so great as to visibly shake the patient's head, or the whole body, and, in some cases, even the bed upon which he lies. More or less pain in the region of the heart is a common symptom. The præcordial dullness may extend from the second to the eighth rib, and if the dilatation be considerable will be of greater extent horizontally than longitudinally. And the systolic and diastolic sounds will be abrupt, greatly louder, of greater extent, and the first sound of a higher pitch than natural. If valvular disease be

present, a systolic bellows murmur will be superadded to the above signs.

Hypertrophy of the right ventricle is, as a general rule, associated with more or less dilatation of its cavity, and when well-marked, is seldom met with, unless in conjunction with hypertrophy of the left also, and is not so readily detected as the latter. The inferior portion of the sternum will be arched, there will be greater epigastric fullness than natural, and the left costal cartilages may be more projecting than the right. Percussion will detect dullness, beyond the right margin of the sternum, depending, however, upon the extent of the hypertrophy, and the dullness will also extend considerably to the left. Greater dyspnœa will exist, and the heart's impulse will be found situated more to the right against the sternum, and ensiform cartilage. The systolic sound at the ensiform cartilage will be duller than natural; the diastolic fuller, stronger, and more accentuated. The pulse is of natural force notwithstanding the strong action of the heart. Engorgement, and œdema of the parenchyma of the lungs, may be present, as well as pneumonia, hemoptysis, and pulmonary apoplexy, but with these latter, valvular disease is also present.

Hypertrophy of the auricles seldom if ever occurs alone, but is usually associated with valvular abnormality, and there are no positive physical signs indicating the enlargement.

In an examination of the physical signs of the various affections of the heart, great care should be taken not to be misled by somewhat similar signs associated with pleuritic and pulmonary diseases.

The *prognosis* of the cardiac hypertrophy depends upon its amount and accompanying morbid states. The simple form is much more favorable to a prolonged existence when of medium amount, and when at the same time, proper hygienic measures are observed. The more extensive the hypertrophy, the less favorable will be the prognosis, and still more unfavorable will it be when associated with dilatation. Dilatation renders the prognosis more serious in proportion as it exceeds the hypertrophy. It is impossible to form an idea of the length of time a person may live with this disease, it varies from a few months to several years, and may destroy the patient suddenly, or he may die from some other disease. Much depends upon the accompanying morbid conditions, the surroundings of the patient, and his management of himself. A physician, a particular friend of mine, was affected with eccentric hypertrophy for thirteen years, when a severe diarrhea carried him off.

Post-mortem examination reveals various conditions, according to

the extent of the disease, and its concomitants. The heart is of greater size and weight than natural, the walls of the affected ventricles being two or three times thicker than when normal, the thickness being, as a general rule, uniform when it is the left ventricle, which is enlarged, and irregular when it is the right, the thickness, in the latter case, being much more considerable near its base. The substance of the hypertrophied walls when cut into will be firmer than natural, and the cut surfaces will present a redder appearance. In connection with the hypertrophy, there may also be observed, more or less dilatation or diminution of one or more of the cavities; false membranous layers between the heart and pericardium; fatty changes; thickening of one or more of the valves; hypertrophy of the columnæ carnæ; calcareous, ossific, or cartilaginous concretions in the aorta, or valves; with diseased states of the pleura, lungs, bronchial tubes, and other organs; but these various abnormal conditions are only the concomitants, and are not always necessarily connected with the hypertrophy.

It is very doubtful whether *treatment* can effect much more than palliation, perhaps, it may moderate, or check the tendency to farther increase, but no more. And were it possible to cure the disease even in its simple form, a tedious, persevering, and rigid course of therapeutical and hygienical measures, continued for several years, would be absolutely required; and, experience has proven that with the best treatment, and under the most favorable circumstances, it is a very difficult thing to persuade a patient with chronic disease to persevere in the treatment of any one physician for more than four or six months at the farthest, unless some decided and well-marked change for the better has occurred, and which, with many diseases, is an absolute impossibility. Hence, a disease which might possibly be cured under the long-continued attendance of a medical man who has closely watched its progress and its characters when under the influence of certain medicines and hygienic treatment, will, probably, never be cured under the attendance of several physicians in succession, each one of whom will necessarily consume a certain amount of time in learning those peculiarities of the diseases, already more or less perfectly ascertained by the previous medical attendants. In many cases, the physician is discharged, just about the period when his knowledge of the disease and its requirements is at its maximum.

In the therapeutical treatment of cardiac hypertrophy, general blood-letting, and all depletive or other measures that debilitate must absolutely be avoided. Cupping or leeching over the region of the heart, to a moderate extent, may relieve pain, or powerful

ventricular excitement, but it is a course I rarely pursue. And even should the patient be highly plethoric, I place more confidence in attentions to the surface without causing profuse diaphoresis, regularity of the bowels without purgation, moderate diet, and diuretics. Yet, there will be cases, in which an action of the liver, or even of the kidneys, will be more thoroughly effected by purgatives than by diuretics, and a tendency to congestion in the system be more fully and permanently prevented.

Various sedative agents have been recommended from time to time for the purpose of tranquilizing the palpitations, and lessening the painful and oppressive sensations in the cardiac region. There are but two which I am in the habit of using, viz.: 1, The Alcoholic Extract of *Conium Maculatum*, which may be given in one or two grain doses, repeated every half hour or hour, until the desired quietude is produced, and which I consider the best agent in a majority of cases, especially where there is much nervous agitation; and, 2, The Alcoholic Extract or Tincture of *Aconite Root*, which may be given in doses of one-eighth of a grain, or ten drops, every three or four hours. The Tincture of *Gelsemium* has also been highly lauded, and, from its influence upon muscular tissue, I should judge it to be valuable, but I have not employed it in this disease.

I have found the Tincture of *Sheep Laurel*, in doses of ten or twenty drops, three or four times a day, decidedly useful in many cases; or, it may be given in the following combination: Take of Tincture of Musk, Essence of Cinnamon, Ether, and Tincture of *Sheep Laurel*, each, equal parts; mix. The dose is from ten to thirty drops, repeated three times a day. (*See further on, Palpitation.*)

In combination with these internal agents, local applications should be made over the region of the heart, as, Plaster of *Aconite*, Compound Plaster of *Belladonna*, and, in some cases, *Croton Oil* Liniment, or even the Compound Tar Plaster. Some caution must be had in the employment of these local means, where cupping or leeching is resorted to, at least until the slight wounds produced thereby have cicatrized.

Iodine, Iodide of Ammonium, or Chloride of Gold and Sodium, may be administered internally, with a view and a hope of at least checking further tendency to hypertrophy. A very useful preparation is the following: Take of carefully dried Ox Gall two drachms, Bromide of Ammonium two drachms, Extract of *Conium* one drachm, pulverized Black Cohosh a sufficient quantity to form a pill mass; mix, divide into sixty pills, of which one is a dose, to be repeated three or four times a day. It will be better to admin-

Administer one of these agents for a few months, and then employ the other, and so on alternately. And, in conjunction, diuretics from time to time must not be omitted. The shocks from an electrical or electro-magnetic battery must be avoided, unless they are very moderate. Hydragogues should not be employed, unless dropsical symptoms are present, and then with great care; diuretics are to be preferred when they will act. Measures that may produce anemia must be avoided; and should anemia be present, tonics and chalybeates must be exhibited, as the Elixir of Iron and Cinchona.* If chronic catarrh, chronic bronchitis, pulmonary emphysema, dropsy, or a tendency to apoplexy, etc., be present, the proper preventive or remedial measures must be resorted to.

The following will be found an excellent remedy in cardiac hypertrophy: Take of Iodine, finely pulverized, six grains, Alcoholic Extract of Conium, Alcoholic Extract of Cimicifuga, each, twenty-four grains, finely powdered Xanthoxylum a sufficient quantity to form a pill mass of proper consistence; mix, divide into twenty-four pills, of which three or four may be taken daily, or, one pill every three or four hours.—Recently, I have derived considerable benefit from the Tincture of Cactus Grandiflora.

As to the hygienic measures, the patient must avoid all exertion or excitement, whether physical, emotional, or intellectual; the powerful passions, as, anger, grief, joy, etc., must especially be guarded against. Mental depression must be equally avoided. Cheerful society is advisable, but not where cheerfulness is carried to a degree of excitement. Coition should be rarely indulged in. Exercise must be moderate, in the open air, and principally passive. Late hours at night, as well as rising too early in the morning, are not to be advised. The diet should be moderate, nutritious, and of easy digestion. Contrary to the rule usually laid down, I advise patients with this disease to dispense as much as possible with vegetables, and make use of meats, especially tender beefsteak, and roast beef, with bread sparingly covered with butter, and in my practice it has answered a much better purpose than the opposite course. Alcoholic liquors are to be avoided—though, in some instances, an occasional and moderate use of wine or beer will be advantageous. But, it is better by far for the patient to avoid stim-

* Whenever I refer to the Elixir of Iron and Cinchona, I mean the article now generally prepared by pharmacutists, and which contains soluble Pyrophosphate of Iron, as one of its ingredients. Or, the preparation under Chronic Peritonitis, consisting of Blue Flag, Black Cohosh, Soluble Pyrophosphate of Iron, etc., may be used as a substitute.

ulating fluids as much as possible, using for drink, whenever required, instead of tea, coffee, or milk, small quantities of some pleasant diuretic infusion. The mind should be kept agreeably occupied; and if there is much wakefulness at night, a pill of the Extract of Conium will induce sleep.

ATROPHY OF THE HEART, in which the walls of the heart become diminished in thickness and weight, is of very rare occurrence; it may be the result of wasting or disease, and is met with in phthisis and cancer, or, it may be congenital. The impulse of the heart is of more limited extent than natural, and lacks force; the pulse is small and rather slow; præcordial dullness is less extensive, and there will be a want of vigor throughout the system generally. Very little, however, is satisfactorily known concerning either the symptoms or the treatment of cardiac atrophy. When the atrophy is due to a conversion of the muscle into fatty matter, it is termed *fatty degeneration*, which will be referred to hereafter.

DILATATION OF THE HEART.

Dilatation of the heart is an unnatural expansion of the cavities and orifices of this organ, and is more commonly complicated with valvular disease, and with organic and functional disease of the heart, lungs, liver, or kidneys. So that the dilatation may be present in various degrees, as well as in different combinations. Indeed, in the majority of cases of cardiac dilatation, their history will reveal some prior affection, as, acute rheumatism, syphilis, etc., as well as, perhaps, some present accompanying organic disease of one or several of the organs above named.

Three forms of dilatation have been described by medical writers; the first, being associated with hypertrophy, or where there is an increased capacity of the heart's cavities, with an abnormal thickening of their walls, and which is termed *hypertrophous dilatation*; the second, where, notwithstanding the dilatation, the walls remain of the same thickness as belongs to them in their normal condition, and which is termed *simple dilatation*. To my mind, this second variety is a minor degree of hypertrophy with the dilatation, and hence really belongs to the first form. The third form is that in which the walls of the chambers are greatly thinner than when in a normal condition, and is termed *attenuated dilatation*; in this form, when the dilatation is excessive, the muscular substance of the walls is soft and flaccid, and in many cases loaded with fat. As a com-

mon rule, the dilatation is general, involving the whole heart, or both ventricles, one, however, being more extensively dilated than the other; partial dilatation, or expansion of certain cavities, is rarely met with, and are of much less importance. Partial dilatation is usually confined to the right ventricle, seldom to the left. The affected ventricle (or ventricles) is dilated more in its transverse than in its horizontal diameter, it therefore assumes a globular form, and the heart's apex being consequently almost effaced is not detected without some difficulty.

Dilatation of the orifices, especially the auriculo-ventricular, may be met with as frequently as that of the cavities, and may exist alone or in conjunction with the latter. As a general rule, it only happens when the auricle and ventricle of the same side are simultaneously dilated. As with the cavities, the dilatation of the orifices may exist in various degrees; but when it is of considerable degree the auriculo-ventricular valves become insufficient for their purposes of closing the orifices. Occasionally, the arterial orifices are found slightly dilated.

The *causes* of cardiac dilatation may be found among those circumstances which give rise to an accumulation of blood in the cavities, distending them. The accumulation of blood may be due to an impediment during its passage from the cavities, and with this there will be a weakness of their walls, rendering them insufficient to overcome the resistance opposed to them; hence, dilatation will ensue more or less rapidly, according to the extent of the obstruction, and the debility of the walls. Among these circumstances may be named valvular disease, contraction of an orifice, frequent returns of nervous palpitations, depression of the mind, excessive venery, masturbation, and whatever tends to produce a feeble state of the heart's activity and power. It is, fortunately, by no means a common affection, and is more apt to be met with in persons of a nervous, lymphatic, rheumatic, or scrofulous constitution, who are feeble and delicate, and also among those addicted to vinous or alcoholic drinks.

Cardiac dilatation may also follow inflammation of the heart; rheumatic attacks of this organ, phthisis, asthma, pulmonary emphysema, syphilis, exhausting maladies, chronic bronchitis, asthma, hepatic congestion, and anasarca, are common concomitants of this disease.

Independent of the *symptoms* of co-existing maladies, those of dilatation of the heart will be such as indicate an enfeebled condition of this organ, and they will be found to vary considerably, according to the degree and extent of the expansion, and its com-

plication with other abnormal conditions of the heart and its orifices. It is not necessary to enter into a description of these varied and modified symptoms, a reference to the principal ones which may be observed when the disease has considerably advanced, must suffice. It must be recollected, however, that uncomplicated dilatation of the heart, as well as partial dilatation, are seldom if ever brought before the practitioner for treatment; the dilatation is almost always general, and the symptoms more or less modified by the co-existing morbid conditions.

The pulse will be found permanently irregular, unequal, weak, and generally small; there will be great uneasiness in the region of the heart with distressing palpitations; the patient will become irritable, peevish, and despondent, will lack both physical and mental energy, and will have his sleep disturbed by frequent startings and unpleasant dreams; he will suffer from attacks of chilliness, from constipation, from dyspnœa, and also from orthopnœa, with diminution of the urinary secretion; albumen may frequently be detected in the urine. Asthma, or a wheezing respiration, and cough, together with the difficult breathing, demonstrate the suffering of the pulmonary organs from the venous congestion. From the tendency to this congestion, the liver also exhibits a rapid increase of tumefaction, in a few hours descending far into the abdomen, yet returning to its ordinary size on the subsidence of the congestion. Edematous swellings of the feet and ankles, anasarca, ascites, or hydrothorax may be present; usually one of them. The skin will be sallow, or of a leaden color, especially in the morning, about the eyes and mouth; and the inferior extremities will present a blue or livid appearance. Nausea, and deranged appetite exist in the advanced stages. In addition to which there may be injection of the eyeballs, *muscæ volitantes*, tinnitus aurium, partial deafness, attacks of epistaxis, dull headache, mental sluggishness, drowsiness, and coma. A rupture of the heart may occur under certain circumstances, when there is dilatation of the cavities, with excessive attenuation of the walls, and more particularly, if softening be also present.

In the *diagnosis* of cardiac dilatation we will find the heart's impulse to be feeble, tremulous, and irregular, and it may be more extended than natural, without any arching or bulging of the cardiac region. Dullness on percussion over this region; as in hypertrophy, will occupy a wider space than natural, with a squareness of outline. Auscultation will detect the systolic sound, short, abrupt, superficial, full-toned, and of higher pitch than natural, if the muscular walls of the heart be firm and properly nourished,

while the diastolic sound will be about as usual. But if these walls be soft, flabby, or fatty, the systolic sound will be weak, faint, toneless, and of high pitch, while the diastolic sound will be so faint as scarcely to be heard at the apex. Indeed, the leading physical signs are, increase of the area of dullness over the heart, feebleness of impulse, feebleness and smallness of pulse, feebleness of the sounds of the heart, and absence of true valvular murmur—and, with these, there will be dyspnœa on exertion, pulsation of the jugulars, and a liability to cerebral, pulmonary, hepatic, or renal attacks, with a tendency to dropsy. Should any murmurs be present, they may be due to an impoverished condition of the blood, or to incompetency of the valves, permitting regurgitation.

When the right ventricle only is dilated, the præcordial dullness will extend to the right, there will be a turgid state of the jugulars, and excessive pulsation in the epigastric region. If the walls are very weak, there may be a systolic murmur along the course of the pulmonary artery, from coagulation of blood within the dilated cavity. This partial dilatation is rarely met with.

Dilatation of the auricles may be ascertained by the dullness on percussion over their natural positions. If the right auricle is dilated, the jugular veins will be permanently enlarged and knotty. If the left auricle be dilated there will be signs of mitral disease.

Dilatation of the heart may be distinguished from other cardiac affections by the following symptoms, which are wanting in dilatation:

In *simple hypertrophy* there is a bulging over the cardiac region, the impulse is distinct and thrusting, the heart is lowered, its action is more forcible, the systolic sound is dull, muffled, and prolonged, the systolic silence is short, and the pulse is full, strong, and resisting. In *eccentric hypertrophy* similar symptoms are present, but the systolic sound is loud and powerful; however, if the dilatation predominates over the hypertrophy, the symptoms will then partake more of those of dilatation.

Mitral regurgitant disease will manifest a more forcible impulse, and its peculiar systolic murmur at the left apex; if, however, a murmur exist without the mitral valves being diseased, the signs of dilatation, if present, will enable us to distinguish the malady.

Chronic effusion of the pericardium gives rise to friction sound, the præcordial dullness partakes more of a triangular outline, and the impulse will be undulating.

The *prognosis* of dilatation of the heart is always unfavorable; a slight degree of expansion may be present without lessening the

period of life. But when the cavities are greatly dilated, with urgent dyspnœa, great constitutional debility, pulsation of the jugulars, impoverished blood, and œdema or dropsy, life may terminate in from six to twenty months.

When the expansion is moderate, it produces little inconvenience, can not be so readily detected, and requires but little treatment. A proper course of hygienical and therapeutical measures may prolong life considerably.

A *post-mortem* examination reveals an enlargement of the chambers of the heart, and, sometimes, also of the auriculo-ventricular orifices, with more or less grumous coagula in the dilated cavities. If the walls are hypertrophied, the appearances named under Hypertrophy will be observed. If the dilated walls be thinned, they may be found reduced to a line or two in thickness, and consisting of a soft, flabby tissue, sometimes readily broken down by the mere pressure of the finger, and presenting a darker red color than natural, or paler, or mottled yellowish-brown. If this softness of the tissue is unequal, the formation of an aneurismal-like pouch may be perceived at the softer and more yielding point. The fleshy columns are usually stretched and spread out. If the muscular walls be microscopically examined, the fiber will be found somewhat granular, with a diminution of its striated character, and fatty or other adventitious matters may also be present.—In connection with the above appearances there may also be evidences of other abnormal conditions, as, pericardial adhesions, valvular disease, etc., as well as diseased states of the other organs heretofore referred to as co-existing with the dilatation.

The indications of *treatment* are, to remove the cause of the dilatation if this be possible; to tranquilize the circulation, and to relieve the heart of the blood which overloads or oppresses it; to strengthen the walls of the heart, so that it may be enabled to expel the contents of its cavities, and oppose the further progress of the dilatation; and to diminish pulmonary, hepatic, and other congestions, without enfeebling the patient.

Dilatation arising from valvular disease, or from pericardial adhesion, can only be palliated, not cured. But when it arises from prolonged muscular exertion, violent mental emotion, repeated attacks of bronchitis, profuse hemorrhages, exhausting diseases, anemia, constrained postures, playing on wind-instruments, etc., much benefit may often be derived from treatment, provided the disease is not in an advanced stage, the walls of the cavities are not thinned or softened, and the patient has not reached his fortieth year.

To tranquilize the circulation, and to relieve the heart, the patient must be kept as quiet as possible, avoiding all physical and mental excitement, although moderate exercise without inducing fatigue is advisable, such as walking short distances, riding in a coach, etc. The diet must be regulated, selecting nutritious food, easy of digestion, and such as will not occasion uneasiness of the stomach, acidity, flatulency, or constipation; full meals must not be permitted as they are apt to occasion palpitation. Animal food is decidedly preferable to vegetable. As to fluids, the less drank by the patient the better will it be for him, except it be for the purpose of producing diuresis, whenever this is indicated. A dry air is preferable to a moist one. The bowels should be kept free either by diet, or by mild laxatives; the renal secretion must be kept as normal as possible by diuretics, and the skin must be maintained in a healthy condition by occasional bathings, and the wearing of flannel. The feet must be kept warm and dry. And all dyspeptic symptoms must be combated by remedies which will neither enfeeble nor excite. The Extract of Belladonna, or of Conium Maculatum, may be used both internally and externally to tranquilize excited action; but aconite, digitalis, and cupping or leeching are to be positively interdicted. The Alcoholic Extract of Cimicifuga or its infusion will be found useful as a tonic and tranquilizer.

To strengthen the walls of the heart, in addition to the preceding measures, tonics must be given, and everything calculated to debilitate the system must be avoided. A very excellent non-stimulating tonic may be prepared, as follows: Take of the bark of the root of Wahoo, root of Black Cohosh, each, two ounces, Bloodroot, Pleurisy Root, each, half an ounce; mix, make into two quarts of syrup, and give one or two tablespoonfuls, every three or four hours. In a few cases, where the patients had reached adult age, were anæmic and feeble, with a tendency to dropsical infiltrations, the disease having made but slight progress, I have met with the most decided benefit from the employment of the Elixir of Iron and Cinchona, in conjunction with the Compound Infusion of Parsley. At the commencement of the disease considerable benefit may be derived from preparations of Iron conjoined with Strychnia in doses varying from one-fiftieth to one-twentieth of a grain. The Tincture of Cactus Grandiflora in doses of from ten to forty drops three times daily, has been highly recommended, in all heart diseases; it is employed in conjunction with the other measures pursued. I have certainly found it useful in several cases. Prof. J. M. Scudder prefers adding a

fluidrachm of the tincture to four fluidounces of water, of which the dose is a teaspoonful, three or four times a day.

To diminish pulmonary and other congestions we must rely entirely on expectorants, diuretics, and gentle diaphoretics, together with frictions over the surface, warmth and local stimulants to the inferior extremities, and quiet on the part of the patient in a moderately warm and dry apartment. Dry cupping and sinapisms over or near the congestive organ will also be of service.

Paroxysms of dyspnœa may be relieved by the Ethereal Tincture of Lobelia, Indian Hemp, or, some of the non-stimulating measures named under the treatment of Asthma; or by the Liniment of Oil of Turpentine, Oil of Amber, etc., named under Hypertrophy. The Tincture of Cactus has also afforded singular relief. Dropsy, by the means named under Hypertrophy; the Compound Infusion of Parsley will frequently be found beneficial, when its stimulating influences are not so great as to contra-indicate its use. More ordinarily, however, when the disease has advanced so far as to give rise to dropsical effusions, a temporary benefit is the most that can be expected from treatment; and more especially when disease of the valves and orifices is also present. Flatulence must be corrected by carminatives, with alkalies or absorbents conjoined, if gastric acidity be present. The employment of anæsthetics for any purpose whatever, is positively dangerous.

FATTY DEGENERATION OF THE HEART.

This disease does not consist in the deposition of fatty matter in the areolar or connective tissue of different parts of the heart, nor in fatty infiltration under the pericardium, amid the muscular fibers and under the endocardium, conditions which sometimes occur, but of which we have no positive methods of diagnosis and treatment. It consists wholly of a metamorphosis or conversion of the elementary particles of the muscular substance of the heart into oily or fatty matter. The disease may exist in association with hepatic diseases of various kinds, hemorrhagica purpura, scorbutus, Bright's disease, chronic rheumatism, etc., and especially with white softening of the brain, of the spinal cord, fatty softening of the kidneys, and gout; but, it must be borne in mind, that these affections may also be present in many instances, while the heart remains sound. The disease may also exist in thin persons, as well as in those who are corpulent. And although the young may labor under it, it is much more common to those of middle and advanced age.

The *causes* of fatty degeneration are not well understood. All persons are liable to it, but especially those who are sedentary in their habits and indulge in the luxuries of the table, and in smoking tobacco; it has also occurred among those who were very abstemious and careful in their mode of living. Males appear to be more liable to it than females. Frequent venesections appear to dispose to it, as well as the constant use of vinous and fermented liquors. The disease appears to be due to a mal-nutrition resulting in atrophy of the muscular elements and a molecular deposition of oily matter.

The *symptoms* are very variable, and are by no means positive; and often, if not *generally* as the rule, the fatty metamorphosis will have advanced considerably before any well-marked characters will be manifested. Thus, there will be a remarkably slow pulse, sometimes as low as forty-five or fifty beats in a minute, or it may be frequent and irregular; (Dr. H. Kennedy considers the pulse a very important aid in the diagnosis, whatever may be its number of beats; the heart being enlarged, so is the pulse; and when he finds the pulse large and compressible, passing sedately or lazily under the finger, not conveying the idea of strength, but rather of action without power, he considers himself justified in concluding that fatty heart exists—but he does not, of course, exclude other symptoms, in order to render the diagnosis more perfect); general debility; sense of nervous exhaustion; frequent sighing; the least exercise gives rise to cardiac uneasiness, or dyspnœa, or both; the appetite as well as the digestive powers are feeble; the bowels costive; the liver enlarged; the general tissues soft and flabby; muscular power at its minimum; sallowness or lividity of the face; slight œdema of the feet and ankles; orthopnœa; apnœa; asthmatic respiration; lowness of spirits; peevishness; cough; palpitations; cardiac pain; attacks of syncope from the slightest causes; choking sensations; loss of sexual power; mental debility; failure of memory; feebleness or failure of sight, hearing, and taste; singular sensations in the head; apoplecticiform, or epilepticiform attacks, etc. Arcus senilis is frequently present, and in conjunction with some of the other symptoms may become a valuable indication; but then it may exist independent of any heart disease, as, an accompaniment of old age, or of some disease of other organs. Patients laboring under fatty cardiac metamorphosis frequently anticipate and correctly prophesy a sudden death. These symptoms are not always present; it has often happened that the degeneration has advanced to a considerable extent before it was suspected, and even then not until some unusual

exertion had developed some of its symptoms. Rupture of the heart is by no means an uncommon occurrence. Paget observes: "The principal characters which all these cases seem to present is, that they who labor under this disease are fit enough for all the ordinary events of calm and quiet life, but are wholly unable to resist the storm of a sickness, an accident, or an operation." Persons have been met with of great muscular powers, and presenting none of the symptoms of this disease until shortly before death, in whom a post-mortem examination has detected an extensive fatty degeneration of the heart. In many instances, the first symptom experienced by the patient, is, a sensation of great distress and pain in the region of the heart; he carries his hand over the organ as if to relieve his suffering, falls into syncope, and either dies in a few minutes, or lives for a short period only, with frequent attacks of syncope, cramps, pain, dyspnœa, and a haggard, cadaverous countenance.

The physical signs possess no more positiveness than the symptoms just referred to. The heart's impulse is weak, and indistinct, as if the organ were lazily projected forward; the præcordial dullness remains of normal extent; the systolic sound is weak, short, and relatively high-pitched, is followed by a long systolic silence, and then a feeble but relatively distinct diastolic sound. If the disease be complicated with dilatation or valvular disease, the physical signs will partake more or less of the character of the accompanying disease, according to its extent, and the diagnosis, which is at all times beset with difficulties, be rendered still more obscure.

If the præcordial dullness be not enlarged, if congestion or dropsy be present, and distension and pulsation of the jugulars, the case is dilatation, and not fatty degeneration.—No murmur is present in the fatty disease, unless there be a co-existing valvular malady.—If there be prominence of the præcordial region, a triangular shape of the præcordial dullness, with distinct heart-sounds at the summit of the sternum, the case is one of pericardial effusion, or hydropericardium. The apoplectiform attacks of fatty degeneration of the heart differ from uræmic coma, in being frequently accompanied with stertor; and from ordinary apoplexy, by being of much shorter duration, attended with paleness of the face, and manifesting no subsequent disposition to paralysis.

The *prognosis*, when fatty degeneration of the heart is detected, is always serious; yet it is not always fatal, for an extensive degeneration has been known to exist, without presenting any diagnostic symptoms, and in which death was occasioned by other

causes not connected with the heart disease. If the disease can be detected before it has made much progress, and is uncomplicated, the chances for recovery, or permanent amelioration, are greater in proportion to the youthfulness of the patient. If complications be detected, as dilatation, etc., the prognosis is rendered still more unfavorable. In this disease, death frequently occurs instantaneously.

Post-mortem investigation reveals a softened state of the affected muscular tissues, which may be easily torn apart, and the interior of the ventricles presents a mottled appearance of buff-colored spots of a peculiar zigzag form; the affected tissue varies from a very light brown to a somewhat darker color, and sometimes oil globules can be pressed out of it. A similar mottled appearance may be observed beneath the pericardium; and, in very extensive cases of degeneration, a section of the walls of the ventricle will discover the same appearance throughout their entire substance, as well as of the columnæ carnæ. The heart is more commonly dilated, though it may be hypertrophied, present patches of sanguineous infiltration, and, at the softened parts, an aneurismal pouch, or even a rupture may be observed. Disease of the valves may also be present, but this is not necessarily connected with the fatty metamorphosis. Under the microscope, little else will be seen than fat granules and oil globules; the transverse striæ of the muscular tissue being absent or indistinct; the nuclei of the fibers having disappeared; and the muscular fibers being much shorter than natural, and brittle. These fibers will be made more distinctly visible, after the addition of Ether to the specimen under examination, which dissolves the fatty matter and oil.

The *treatment* of this disease will greatly resemble that of fatty degeneration of other organs, viz.: to improve the nutrition of the affected organ; and although we may not expect to restore the disorganized heart, we may do much toward palliating urgent symptoms, checking a rapid advance of the malady, and thus prolonging life. (*See treatment of Softening of the Brain*, page 163, and *Apooplexy*, page 203.) Among therapeutical agents, preparations of Iron and Quinine are the best tonics. I have derived considerable advantage from the internal employment of the Elixir of Iron and Cinchona, or of a similar preparation referred to under the treatment of Chronic Peritonitis, persevered in for a long time, in conjunction with the following: Form a saturated Tincture of Squills in Sweet Spirits of Nitre, of which from half a fluidrachm to a fluidrachm is to be taken every two, three, or four hours, until free diuresis is produced, after which its use may be dispensed with for

a few days, and then renewed, and so on during the treatment. (This tincture is also excellent in that morbid condition of the renal organs common to gross and corpulent persons, which is attended with nausea, and from which sudden death frequently occurs.)—Benefit will frequently be derived from Strychnia, which may be given in powder or tincture, or in the preparation named Citrate of Quinia and Iron with Strychnia. This article stimulates the muscular action of the heart, and is especially useful in cases associated with general weakness, or anemia. The Tincture of Arnica has also been advantageously employed for a similar purpose.

To relieve the dyspnœa, the following preparation will frequently be found advantageous: Take of Oil of Turpentine three fluidounces, pure Oil of Spike four fluidrachms, Oil of Sassafras, Oil of Amber, each, two fluidrachms; mix, and form a liniment. Rub some of this upon the throat, and over the whole of the chest, three or four times a day, whenever severe dyspnœa is present. (*Prof. A. J. Howe, M. D.*) Cardiac pain may also be relieved by this liniment, or by dry cupping over and around the seat of the pain, or by the use of some counter-irritant in the same location.—Apoplectic-form attacks will require the internal use of stimulants, together with rubefacients or counter-irritants to the inferior extremities. Inhalations of Ether or Chloroform, or the employment of direct cardiac sedatives must be avoided, as they may produce serious results.

¶ No exhausting or debilitating measures should at any time be pursued. The bowels should be kept regular, as well as the kidneys; the surface of the body should be bathed daily with a stimulating alkaline liquid, and considerable friction be produced, at the same time, by means of a flesh-brush. All unpleasant symptoms not herein referred to, must be promptly treated upon general principles. Passive exercise in a pure bracing air is advisable when no unpleasant results are produced; it is better, however, not to exercise at all, than to carry it to too great an extent. Tender animal food, avoiding the fat part, is the best diet, and may be used in moderation; port wine, claret wine, or Rhine wine may also be used judiciously to sustain a sufficient vigor of circulation; but fats, fermented liquors, succulent vegetables, amylaceous diet, pastries, soups, milk, and coffee must be avoided.

Long fasting must be prohibited, as well as alkaline drinks; any gastric acidity must be removed by the use of Charcoal or other absorbents. On the appearance of syncope, diffusible stimulants must be had recourse to; and where the pulse is slow, with a tendency to syncope, or apoplectic symptoms, brandy or wine must be freely used,—being governed rather by the effect these stimulants

produce, than by the quantity given. Tobacco smoking must positively be dispensed with. Physical and mental quietude must be positively enjoined.

There are several other diseased conditions of the heart, as well as of its orifices, valves, and arteries, which have been described by pathologists, as, *Anemia*, *Congestion*, *Accumulations of Blood in the Cavities*, *Extravasations of Blood in one or several parts of the Heart*, *Polypus Formations*, *Œdema*, *Softening*, *Induration*, *Calcification*, *Tuberculous Depositions*, *Carcinoma*, *Parasites*, *Aneurisms*, etc., and though some of them may be detected, or their presence be suspected by the physical signs, yet, as a general rule, but little is known relative to their causes, symptoms, or treatment; and, indeed, they are beyond the power of art. This passing notice, therefore, is all they require in this work, and to those of my readers who desire full information concerning them, I would recommend the various valuable monographs upon Diseases of the Heart, which have of late years been presented to the profession.

DISEASES OF THE ORIFICES AND VALVES OF THE HEART.

These are among the most serious diseases of the heart, and are met with in quite a number of instances of organic cardiac diseases, either as a cause, or as an effect. They are due to inflammations, especially those of a rheumatic or gouty character, atrophy, abnormal growths, morbid deposits, or degenerations, etc. In a practical point of view, it is of very little importance to determine whether the disease exists at the right or left side of the heart; whether it be a lesion of the mitral, tricuspid, or semilunar valves; a contraction or dilatation; an ossification; a permanent patency, or warty excrescence. The great practical points are to determine whether the murmurs present are actually due to an organic lesion, and what is the vital and physical condition of the muscular portion of the heart. These diseases present an impediment or obstruction to the circulating current, either by a narrowing or constriction of the orifices producing an obstruction to the circulating fluid, or by a dilatation of the orifices to a degree which renders their perfect closure by their valves impossible, and which occasions a backward current or *regurgitation*; this may also be caused by a diseased condition of the valves which may interfere with their normal play.

In the description of symptoms and diagnosis, presently given, it must be remembered that they principally refer each one to distinct

and separate morbid states; also, that it is rarely the case to find such isolated morbid states, as valvular diseases are almost invariably complicated, that of one valve or orifice with that of another, or with some lesion of the muscular cardiac structure; and these complications or combinations are very numerous. Again, the most prominent physical signs are often due to a more recent and least-developed malady, while the co-existence of a more important one may not be recognized. Fortunately, however, it is not necessary to minutely recognize every point connected with this class of lesions, in a practical view; the important points to determine, as already stated, are, the certainty of valvular or organic disease, as well as the vital and mechanical state of the heart, to the latter of which the treatment will be principally addressed.

Valvular disease is much more frequent on the left side of the heart; it may exist for a long time without causing local or general disturbance; it gives rise to disease of all the cavities of the heart, of the lungs even, also of the brain; and is much more apt to terminate in sudden death than when the disease is on the right side. If regurgitation without obstruction exists, we will be more likely to find dilatation of the heart; if obstruction without regurgitation, hypertrophy is the rule.

The *symptoms* of valvular disease are numerous and varied, and although they do not of themselves give any positive indication of the nature of the disease, yet they should always be taken into account with the physical signs in forming a diagnosis. The principal ones are,—more or less dyspnœa, aggravated by exercise or on ascending a hill or pair of stairs; often orthopnœa; palpitation; irregular cardiac action; a soft and irregular pulse in mitral disease; a hard, jerking, but regular pulse in aortic disease; epistaxis; hæmatemesis, or hæmoptysis; pulmonary congestion, bronchitis, or other lung difficulties when mitral disease is present; when the right side of the heart is affected, dropsy is more common, as, œdema of the inferior extremities, anasarca, ascites, or hydrothorax; and in aortic disease, headache, ringing in the ears, vertigo, syncope, cerebral congestion or hemorrhage. The face is puffed, cheeks flushed and purple, lips congested, and eyes bright. There is usually more or less derangement of the digestive organs, with enlargement of the liver and spleen. Sleep disturbed, with frequent startings, and frightful dreams. There may also be pain in the cardiac region, varying from a slight aching sensation to a most intense pain.

The physical signs will be found to vary, according to the seat of the affection, its combinations, etc. The principal ones only will

be referred to. But first, as to the situation of the valves and orifices: A horizontal line drawn from the inferior margins of the third ribs across the sternum, passes through the pulmonic valves a little to the left of the mesial line, behind which, but about half an inch lower down, lie the aortic valves; the pulmonary and aortic orifices will be below these. A horizontal line drawn along the under edge of the sterno-costal articulations of the fourth ribs will cut across nearly the middle of the length of the mitral valve, when drawn outward and downward by its tendinous cords and columnæ carneæ, and will pass about two or three lines above that portion of the tricuspid valve which most nearly approaches it; the latter valve lying underneath the sternum, and the former immediately to its left. The mitral and tricuspid orifices will be above this line. The mouth of an ordinary-sized stethoscope will cover them all within the circle of an inch and a half or less. And in order to separate the murmurs, the instrument must be shifted an inch or two higher or lower, and then we may determine their character. The particular direction of a murmur is given to it by the orifice from which it is propagated. A murmur conveyed in an upward direction, along the course of the aorta, and which can be heard in the carotids, proceeds from the aortic orifice, and the valve there situated is the valve diseased. If conveyed downward and to the apex of the heart, the auriculo-ventricular orifice is its point of departure, and the valve there situated is the one diseased. If the murmur is conveyed both upward and downward in the directions just named, then it has two points of departure, and both the aortic and mitral valves are diseased. If the murmur be heard passing upward between the second and third ribs on the left side, and can not at the same time be heard in the carotids, it is taking the course of the pulmonary artery, and the pulmonic valve is diseased.

Mitral regurgitation from insufficient mitral valves, in which the blood regurgitates or flows backward, in its passage through the auriculo-ventricular orifices, from a dilatation of these orifices, or from some disease of the valves which prevents them from properly closing the openings. The impulse is strong, and irregular in force and rhythm; a permanent murmur, which may be soft, whispering, hoarse, musical, or whistling, is heard at the left side, being loudest toward the apex, "faintly audible, or inaudible at the ensiform cartilage, the mid-sternal base, and the pulmonary and aortic cartilages—or, below the line level with the nipple, and between the nipple and the left edge of the sternum; more or less clearly audible about and within the inferior angle of the left

scapula, and beside the dorsal vertebræ on the left, from the sixth to the ninth; audible or not round the lateral base of the chest from the cardiac to the scapular region." This murmur always attends the systole of the heart, and is not heard in the arterial trunks; the second sound is natural. The systolic sound at the apex may be more or less completely masked by the murmur, but is usually natural at the ensiform cartilage. The direction of the murmur, referred to above, is also a useful diagnostic mark; it is the one more often met with in practice. The pulse is small, often intermittent, the complexion is livid or icteric, with symptoms of pulmonary or hepatic congestion, and the urine is scanty, high colored, and depositing urates and purpurine especially.

If the orifice is contracted with other cardiac disease, the heart's action will be tumultuous and irregular, the pulse feeble and unequal, with symptoms of pulmonary congestion.—If dilatation and hypertrophy are present, which are the consequences of mitral regurgitation, the impulse and apex-beat will be carried outward and somewhat lower than natural; and the impulse will be augmented in force; and more or less of the symptoms of dilatation with hypertrophy will be superadded to those just named.

Mitral obstruction, in which there is an impediment to the onward flow of the blood, from contraction of the orifices, thickening of the valves, foreign growths, etc. The impulse is irregular and unequal in force; the murmur is of maximum force, is heard immediately above and about the left apex, and takes the same direction as in the preceding case; it does not occur with the systolic sound of the heart, but just previous to it, being pre-systolic or post-diastolic. The murmur is of a blubbery or purring character, generally somewhat rough, and is often confined within a small space, though it is sometimes heard over a considerable extent. However, mitral obstruction may exist, and this murmur be absent. In connection with this murmur, the characters of the pulse, and the symptoms of pulmonary congestion, will be the same as those named in mitral regurgitation.

Tricuspid regurgitation is frequently a result of dilatation of the right ventricle, giving rise to an impediment to the venous circulation. The murmur occurs with the systolic cardiac sound, is of a maximum degree of force just above or at the ensiform cartilage, (at the right apex), and proceeds toward the right, being faintly heard, if at all, in the left apex, and not at all in the left vertebral groove opposite the inferior angle of the scapula. It is usually soft, of low pitch, and seldom masks the systolic sound completely; sometimes it is rough, like sawing or rasping. The diastolic sound

at the right apex is feeble. Tricuspid regurgitation more commonly co-exists with dilation or hypertrophy; venous congestion of the cerebral capillary vessels, apoplexy, jaundice, congestive albuminaria, dropsies, and passive leucorrhea, are apt to attend this cardiac affection.

Tricuspid obstruction is rare; the murmur will be heard in its maximum force at the ensiform cartilage, and occurs with the diastole or second sound of the heart.

Aortic regurgitation presents a murmur which occurs with the diastolic sound of the heart, and is heard more distinctly near the left margin of the sternum opposite the third interspace or fourth cartilage; with a few exceptions, the murmur is conducted to the right, upward, and directly downward. The murmur may also be heard about the ensiform cartilage. The murmur is generally of low pitch, soft, blowing, or almost hissing, and well prolonged, filling the post-diastolic silence. The systolic cardiac sound at the base will be about natural, dull, and often obscured by a soft or harsh murmur. The pulse is large in volume, very compressible, of a splashing or collapsing character, sudden, abrupt, short, jerking, generally regular in rhythm, and, occasionally, attended with purring thrill; powerful palpitation is present, with visible pulsation of the arteries of the head and neck; bruit de soufflet in the ascending aorta, carotids, and subclavians, with *fremissement*. There is little or no dyspnoea, the urine is abundant and clear, and the complexion remains natural for a long time. The disease is more peculiar to the male, occurs during middle age, occasionally in youth or old age, and is attended with a want of vital energy, which disposes to anemia, fatty deposits, tuberculous formations, etc.

Aortic obstruction gives a murmur which occurs with the systolic sound of the heart, and which is heard more distinctly above the base of the heart, at mid-sternum, in the second intercostal space, and which is transmitted upward, more commonly to the right; it is of high pitch, loud, harsh and prolonged; occasionally twanging or somewhat musical and low-toned, and may generally be heard in the carotids of the neck. It indicates an obstruction from narrowness or roughness, etc., of the aortic orifice. When the heart is very weak or the contracted orifice quite smooth, the murmur may be faint or inaudible. The pulse is regular and natural, though if the narrowing be considerable, it will be small, hard, rigid, and concentrated. The effects upon the constitution are not generally observed until the ventricles become affected, or until the blood becomes impoverished, when anasarca may be developed.

A few *general remarks* may now be made relative to valvular diseases. When a murmur, no matter what is its peculiar quality, is heard occurring with, or nearly with, the systolic sound of the heart, it is in all cases, except of aortic disease, indicative of *regurgitation*; when it occurs with, or nearly with, the diastolic sound, it is indicative of *obstruction*. Aortic valvular lesion gives the murmur with the systolic sound of the heart, in obstruction; and with the diastolic sound, in regurgitation. The point at which the murmur is the most developed, as well as the direction in which it is propagated, should always be closely noticed, as we thereby learn the location of the affected part giving rise to the regurgitation or to the obstruction; and in order to ascertain this correctly, we must first determine the position of the heart itself. We must also be aware that two or more of these valvular lesions may co-exist either with or without morbid conditions of the walls and cavities of the heart, and that the sounds and murmurs may thereby be so masked, modified, or annulled, as to present a decided obstacle to a correct and satisfactory diagnosis. Besides, in all our examinations, the previous history of the case, the state of the system, capillary circulation, lungs, liver, kidneys, etc., should always be associated with the physical signs, as aids in forming a diagnosis.—And, again, occasionally valvular lesions may exist, without any murmur being detected. All these murmurs indicate organic lesion, with the exception of that of aortic obstruction, which may be due to anemia, or other inorganic causes, in which cases the murmur is usually soft, not permanent nor uniform, changeable, and there is no enlargement of the heart, and no aortic regurgitant murmur. Tricuspid and pulmonary regurgitant murmurs are usually, not so easily detected, as those of the aortic and mitral lesions.

M. Forget states that dilatation of a cavity always takes place behind the obstruction; and contraction of a cavity before it.

If the pulse beats with hardness and force, it is indicative of hypertrophy with constriction of an orifice. A sharp and compressible pulse, somewhat defective in volume, as well as in persistence when compared with the heart's impulse, is indicative of obstruction. A regular, very compressible pulse, large in volume, and of a splashing character, is indicative of regurgitation. In mitral disease, the pulse is small, and often intermittent; in aortic disease, large, collapsing, and regular. If other affections be present, as, hypertrophy, dilatation, etc., the pulse will partake more or less of the co-existing malady.

Palpitation, and pain in the cardiac region are more common in

aortic diseases than in mitral. Dyspnœa and general dropsy, are more common in mitral than in aortic diseases. Syncope attends aortic disease; apnœa, mitral.

As to the *prognosis*, all valvular lesions are serious, and almost always incurable. Aortic obstruction with a soft murmur, without enlargement of the heart, and without an aortic regurgitant murmur, is less serious than the other forms of valvular lesion. Death generally occurs slowly in all these cases, but it may take place immediately, by sudden syncope in aortic lesion, or by sudden apnœa in mitral; and, with the exception of the occurrence of syncope, life is more apt to remain prolonged in aortic than in mitral disease. As to the length of time a patient may live who is laboring under a valvular lesion, it is impossible for any physician to decide with certainty; the chances for continued existence are greater where the disease has not advanced toward its later stages, and where the patient rigidly observes the necessary hygienical and therapeutical measures. Dilatation renders valvular disease more unfavorable, so does hypertrophy. Indeed, it is to the existence of cardiac enlargement, that danger is to be apprehended, more than to the valvular lesion. Feebleness of murmur, of pulse, and of general nervous power, are very unfavorable signs when co-existent

Mitral disease gives rise to a dilatation, first, of the left auricle, then of the right ventricle, and lastly of the right auricle; and as these conditions gradually progress, augmented quantity of blood in the left auricle occasions pulmonary congestion, and in the right cavities, dropsy from venous congestion, the surface becoming blue or livid, and the veins of the neck being often swoln, with undulatory pulsations. Hypertrophy usually occurs along with the dilatation of the left auricle.

Aortic disease gives rise to a hypertrophy and subsequent dilatation, first, of the left ventricle, then of the left auricle, and, subsequently, if the patient continues to live, of the right side of the heart. The increased quantity of blood thrown into the left ventricle ultimately determines its hypertrophy and dilatation. When, during the progress of the disease, an increased amount of blood is suddenly thrown into the left ventricle, a feeling of distress, faintness, as if death were about to suddenly occur, is experienced by the patient, which continues as long as the partially paralyzed walls of the ventricle are unable to expel the surplus amount of blood in its cavity; and the patient either dies suddenly from an inability of these walls to remove the increased quantity

of blood, or, should the blood be expelled by the ventricular contractions, recovers from his distressing paroxysm and fear of sudden death. But, ultimately, he dies from a similar cause—the walls of the ventricle gradually become more and more feeble, from great distension, and, at last, so feeble and palsied that they cease contracting or are unable to expel accumulations of blood in their cavities.

The *post-mortem* appearances will vary very much according to the character of the disease and its combinations. The heart is usually enlarged, frequently fatty; cavities more or less dilated, and sometimes containing clots, which may likewise fill the aorta and pulmonary arteries. The affected valves may be variously diseased; in some instances, thickened; in others, hardened or ossified, rigid, contracted, with vegetations, etc.; the orifices may be contracted, natural, or dilated; and the cavities will generally be more or less dilated, with hypertrophy of their walls. Sometimes osseous masses of a rough character will be found upon the lining-membrane of the aorta, which vessel may be dilated or constricted. The pericardium will frequently be found adherent. Aortic valvular lesion is generally associated with hypertrophy; aortic regurgitation with dilatation and hypertrophy; and mitral disease mostly with dilatation. And, in connection with these diseased appearances, there will also be observed morbid conditions of the brain, lungs, liver, or kidneys, etc., according to the character and stage of the cardiac disease.

The *treatment* of valvular disease is entirely palliative, and although we may not expect to cure it, we may, by a judicious course, be enabled to ward off or relieve sudden serious attacks, as well as to prolong life. Everything must be avoided that will reduce the system, making use of measures to improve the condition of the blood, to impart nervous and muscular force, and to remove venous congestions or hydropic infiltrations whenever they are present. The agents employed will be similar to those named under Hypertrophy, and Dilatation, according as the symptoms of one of these predominate. The Elixir of Iron and Cinchona, or the preparation containing Soluble Pyrophosphate of Iron, referred to in the treatment of Chronic Peritonitis, will be found particularly suited to a great number of cases.

Cardiac pain, or palpitation may be treated as named under Hypertrophy; dyspnoea, as named under Fatty Degeneration, and Dilatation; dropsy, as named under Hypertrophy—and, in its commencing periods, the Saturated Tincture of Squills referred to under Fatty Degeneration, may be advantageously employed.

Pulmonary or other congestions will require the means referred to under Dilatation.

The Acetate of Potassa will in many cases be found a very excellent diuretic; and, in cases where, from congestion, the kidneys do not respond freely to the influence of diuretics, the congestion may be removed by purgatives, sudorifics, or by sinapisms, dry cupping, or wet cupping over and around the renal region. A combination of the Tinctures of Squills, Digitalis, and Senega will be found frequently beneficial in mitral lesions. This is also useful in congestion of the lungs, in which it acts as an expectorant; but in order to use Digitalis with safety, it must produce diuresis.

In palpitation, especially from aortic disease, without any serious complication, Dr. Barlow recommends a combination of Hyoscyamus, Nitric Ether, and Decoction of Senega. In dropsy, Elaterium will be found a valuable hydragogue, but care must be taken not to exhaust the system.

Stimulants will usually be found more beneficial in aortic lesion than in mitral; in the latter, although the pulse is much more feeble than in aortic lesion, they are apt to augment the palpitation without any corresponding increase in the strength of the pulse. In these cases, we can relieve the congested condition of the circulation better by cathartics, diuretics, and expectorants.

Syncope, which is more common in aortic lesion, is relieved by external and internal stimulants, and by placing the patient in a recumbent position with the head considerably lower than the body and limbs; it is attended with cerebral anemia, as witnessed in the pallid countenance, and the frequent premonitory attacks of giddiness and vertigo. If the face shows signs of vascularity or congestion, instead of these means, cool or tepid water should be applied to the head, together with warmth and stimulants along the spinal column and to the extremities. Likewise producing catharsis as soon as possible. Great care should be taken in syncopal attacks, as well as in apoplectic, to determine whether they be associated with some disease of the heart, as, hypertrophy, dilatation, etc. The region of the heart, as well as the character of the pulse should be ascertained; a strong action of the heart, with marked impulse, and a strong, full pulse, will indicate the complication of the cerebral with a heart disease in apoplexy. While a small, weak pulse, or a vibrating, jerking pulse, with pallid countenance, previous vertigo, or congested states of certain organs, together with signs of valvular lesion, also indicate a similar complication. But, in the first instance, the treatment will be more of a depletory character;

while the latter will require a more stimulating and sustaining plan of treatment.

Cardiac apnœa is a suppression of respiration, attended with darting or cramp-like pains in the chest, coldness and paleness of the surface, and sometimes more or less spasm, and even pain in the muscles in various parts of the body. The patient feels as if his chest were stiffened and compressed, and often manifests movements as if to procure relief, especially when the attack is not so severe as to prevent him. The heart acts irregularly. When attacked by apnœa, the patient should be placed in a half-sitting posture, and, if necessary, be removed to a situation where he can have an abundance of air. Warmth and stimulation should be freely applied externally, and stimulants be administered internally, especially alcoholic. Or, the following may be used: Take of Extract of *Conium Maculatum*, Camphor, Capsicum, each, one ounce, Oil of Cajuput one fluidounce, Hoffman's Anodyne one pint; mix, and form a tincture. The dose is from twenty to sixty drops, every few minutes, in a little sweetened water. It is an admirable diffusible stimulant, useful for many other purposes.—The Tincture of *Cactus Grandiflora* has been found of great service in these cardiac affections; it may be employed alone, or combined or alternated with the other remedies that are administered. Its dose is from ten to forty drops, three times a day, and continued for many months, as long as no injurious results follow its use.

The bowels must be kept regular in these valvular lesions, and the functions of the kidneys and of the skin be properly maintained. Purgation should be avoided as much as possible, (except to relieve congestion), until dropsical infiltrations occur. The diet should be the same as named for dilatation and hypertrophy, being careful never to have the stomach entirely empty, nor at all loaded at any time. Small meals frequently repeated are the best. Everything calculated to increase the action of the heart should be avoided; and, indeed, the principal and important object of the patient's life, paramount to everything else, should be, a rigid attention to, and close observance of, all therapeutical and hygienic measures, mental as well as physical, that are absolutely necessary to prevent serious and sudden attacks, as well as to prolong life to the utmost.

FUNCTIONAL DISEASES OF THE HEART.

PALPITATION.

Palpitation of the heart is a symptom of various diseases and conditions, often constituting so prominent and important a part of them as to require a separate consideration; it is characterized by an increase of the impulse and sounds of the heart; it may occur without any irregularity in the heart's rhythm, the palpitation being a simple, full, uniform, powerful beating of the heart; or, it may occur with irregular action of the heart, the palpitation being rapid, violent, confused, and irregular. In either case, the heart's action may be so severe as to visibly shake the patient, and even to produce distressing sensations. Palpitation, as we have noticed in the preceding pages, attends several organic diseases of the heart; but it may also be functional or sympathetic.

I. *Palpitation with regular cardiac rhythm* will be noticed in this section; that occurring irregularly will be referred to in the subsequent one.

The *causes* of palpitation are numerous; it may arise from deranged or impaired nervous power, the consequence of intense emotions or passions, excessive study, habitual use of alcoholic drinks, tobacco, strong tea or coffee, masturbation, venereal excesses, spermatorrhea, excessive or enfeebling discharges, lack of proper nourishment, etc., and frequently attends intercostal neuralgia, epilepsy, hysteria, chorea, spinal irritation, and other nervous maladies. It may also arise from sympathy with excited or irritated organs at a distance from the heart, or by a reflex action, as, in dyspepsia, irritable conditions of the stomach or bowels, certain kinds of food, hepatic irritation, worms, menstrual or ovarian derangement, etc. A plethoric, anemic, rheumatic, or 'gouty condition may also occasion palpitation.

The *symptoms* of palpitation are easily made out; the heart is found to act with greater force than natural, of which the patient is fully conscious, feeling its action, and often hearing its sounds; while the practitioner can detect it, both by the hand placed over the cardiac region, and by the ear. This excited action of the heart may occur previous to, during, or subsequent to more or less exertion, mental emotion, or meals, etc.; and it may take place suddenly or gradually. There are frequently associated with it, however, other more or less unpleasant sensations, as, a choking or smother-

ing sensation, or, as if the heart were jumping into the throat, præcordial anxiety, faintness, partial or complete syncope, more or less uneasiness, soreness, or pain in the region of the heart, a hurried breathing, protrusion of eyeballs, coldness of extremities, ringing in the ears, headache, vertigo, etc.

The physical signs are, an impulse felt by placing the hand on the cardiac region, which may be of a heaving character, or may resemble a blow or a slap; the apex being in its natural location. Præcordial dullness generally natural, but sometimes extending to the right of the sternum, never upward. The first sound is loud, abrupt, and short, and may be heard by bystanders; the second is of lower pitch than natural, and is often reduplicated. If anemia be present, a whirring murmur may be heard, termed *bruit de diable*, which somewhat resembles the noise made by a humming top; it does not correspond with the pulsations, nor does it intermit, as is the case with the murmur in organic cardiac disease, and it may likewise be heard in the vessels of the neck. "This murmur is usually louder at the left side, occurs with the systolic sound, and may be heard in the course of the aorta." (*Stokes*.) The pulse at the wrist may be natural, or less than natural, abrupt, quick, full, and heavy, or of a beating character, resisting in the vigorous, but easily compressible in those laboring under anemia.

Sometimes the paroxysms of palpitation occur at regular or irregular periods, from a few minutes to four or five days; at others, they only occur under the influence of mental or physical excitement; again, some persons are never perfectly free from them.

The *diagnosis* of functional palpitation is not so readily arrived at as some writers would lead us to believe, because similar symptoms to those described often occur in organic diseases of the heart, and if we rely upon these only, we may be sadly mistaken. In order to arrive at a satisfactory diagnosis, we must inquire into the previous history of the patient; whether his age, general appearance, and history favor or not the suspicion of chronic organic disease; ascertain the presence of anemia, spinal irritation, the tendency to epilepsy; the habits of the patient as to a sedentary or active life; his moral bearing, his temperate or intemperate habits, excessive nervousness, etc.; we must also observe the character of the vital symptoms present; the point where the murmur is heard the most distinctly, its duration; the state of the heart's general excitability, the extent of præcordial dullness; the presence of murmurs, the time of occurrence and character, the absence or presence of dyspnoea, congestions, dropsical infiltrations, etc.; as

well as the degree of accordance existing between the general condition of the patient's health, and the cardiac symptoms, supposing these latter to be due to organic disease. By this means, we will be enabled to arrive at a more correct and reliable diagnosis.

The *prognosis* of palpitation is favorable in all those cases in which the causes may be removed, as, when due to anemia, sedentary habits, excesses, nervous irritability, worms, etc.; and it is more or less unfavorable when it is due to, or is associated with, epilepsy, spinal irritation, masturbation, intemperance, or other causes which are less amenable to treatment, or less likely to be overcome.

The *treatment* of this form of palpitation will depend considerably upon its causes, or its association with other affections. If the palpitation be due to anemia, the continued use of some ferruginous preparation, as, Elixir of Iron and Cinchona, etc., will be of benefit,—or, if the patient be of a strumous habit, the iron may be combined with antistrumous agents, as, Iodide of Iron, Bromide of Iron, etc. The addition of Iron to the Compound Syrup of Yellow Dock, in a similar manner to the mode of forming Elixir of Iron and Cinchona, will be found a very valuable preparation in these strumous cases.* If epilepsy be present, no great amount of benefit can be expected until this disease be cured; and the same may be said of other attending maladies, as spinal irritation, worms, spermatorrhea, chorea, menstrual derangements, excesses, intemperance, etc. Sedentary persons must lead a more active life; and all exciting causes must positively be avoided.

Acidity of stomach must be neutralized by the use of Prepared Charcoal, Carbonate of Ammonia, or Magnesia. Antispasmodics and tonics may be employed to overcome excessive nervous excitability. The functions of the skin and of the kidneys must be

*Take of Yellow Dock Root, in fine powder, *sixteen Troy ounces*; bark of the root of False Bittersweet, in fine powder, *eight Troy ounces*; American Ivy, Figwort, each, in fine powder, *four Troy ounces*. Mix these articles together, and thoroughly moisten them with Alcohol, and allow them to stand for twenty-four hours; then transfer to a percolator, and gradually add Diluted Alcohol, until the liquid passes but very little impregnated with the properties of the medicine. To this, add Glycerine *sixteen Troy ounces*, and distil or evaporate the mixture, by a gentle heat, to two pints; in which dissolve of the Soluble Pyrophosphate of Iron, *two hundred and fifty-six grains*. The dose is a fluidrachm, to be repeated three or four times a day. This preparation may also be made by percolating through the above powdered articles, a mixture of equal parts of Glycerine and Water, and when two pints have been obtained, add the iron preparation. It is valuable in all cases where a chalybeate, tonic, and alterative preparation is indicated. I now for the first time make it known to the profession.

properly attended to, and the bowels be kept regular. The diet and exercise must be in accordance with the condition of the system and the degree of cardiac excitability, as well as with the maladies with which the palpitations may be associated. All kinds and sources of excitement must be avoided. Wherever pain or soreness is found to exist upon pressure, either at the occipital region, or along the spinal column, active rubefacient liniments, and in some cases, even the Croton Oil Liniment, or Compound Tar Plaster, should be applied upon these tender points. To relieve the paroxysm of palpitation, the same treatment may be pursued, as named for relieving this symptom, under Hypertrophy, as well as Dilatation of the Heart. In persons who have led intemperate lives, the employment of the Trisnitrate of Bismuth, in conjunction with an infusion of equal parts of Quassia, Aletris Farinosa, and Asclepias Incarnata, slightly acidulated with Sulphuric Acid, will be found very useful in overcoming the abnormal condition of the stomach.

II. *Palpitations which are irregular in rhythm and force*, are of a much more serious character than the preceding variety, and generally arise from similar causes. Sexual excesses, masturbation, intemperance, and other irregularities, are among the more frequent causes. Much care is necessary to determine whether or no this affection be associated with some organic heart disease.

The *symptoms* of this form of palpitation are somewhat similar to those heretofore named; but, instead of occurring at the natural periods of the heart's contractions, the palpitations are irregular both as to force and rhythm. They may be remittent, regularly or irregularly intermittent, or present certain irregularities at fixed intervals. At one time the palpitations occur with an increased force, at another with a diminished; the motion of the heart is frequently more rapid at one time than at another; and the pulse will be found to be involved in these cardiac derangements,—thus, at one period the pulsations at the wrist may be natural or lower than natural, and suddenly rise to a hundred and fifty or more per minute, with an inequality of force, and an irregularity of rhythm. Indeed, all these conditions may be met with under the most varied forms.—In connection with the derangement of the heart's action, there may also be a sensation of heaviness, sinking, oppression, uneasiness, or more or less pain at the cardiac region, or pallid countenance, dyspnœa, thirst, nausea, vomiting, more or less disposition to syncope, ringing in the ears, dimness of vision,

a feeling of alarm, and a tendency to diarrhea, or profuse diuresis. If the difficulty is due to sexual excesses or masturbation, there will be tenderness upon pressure over the suboccipital region, as well as along all or a part of the cervical vertebræ, and a dull pain, or of an aching character, in the back part of the head, will be complained of by the patient.

The physical signs are a feeble, or irregularly forcible, fluttering impulse, which may be detected by the hand or ear; and, in some instances, the impulse will convey a jogging, rolling, or trembling sensation. Frequently, instead of the systolic and diastolic sounds being single, they will be double, and this reduplication may be heard at a limited spot, or over a considerable extent. The systolic sound is usually short and sharp; and the rhythm of the heart is not natural. These palpitations come on paroxysmally, and may vary in duration and in their periods of attack, the same as the preceding variety. They also require similar carefulness of investigation in regard to their *diagnosis*, which is not always easily arrived at.

The greater the departure of the heart's action from its normal force and rhythm, the more unfavorable will be the *prognosis*, as a general rule; for it is apt, in the more irregular instances, to be associated with some organic lesion, and especially among patients of middle age. Yet, instances may occur, in which no such lesion exists, and no immediate unfavorable results will take place; but, it is extremely difficult, if not impossible to isolate these instances. An abnormality in the force of the heart's action is more unfavorable than when existing in its rhythm. In forming a prognosis, all the symptoms, local, constitutional, and physical should be taken into account, carefully comparing them, and giving to them their proper value, both individually and collectively. For if we treat this symptom as a nervous affection when it is actually associated with an organic cardiac lesion, we may increase our patient's sufferings, and hasten his death.

If, after a careful investigation, we conclude that the affection is not connected with a structural disease, but is nervous or sympathetic, our *treatment* will depend considerably upon its cause. The first indication of treatment is, to remove the exciting cause of the affection, making use of the proper means to overcome intestinal irritations, mental overexertion, excesses, or intemperance, as well as other causes; and the various abnormal conditions resulting from these causes must also be remedied. The second indication is, to impart vigor to the system, and to give increased nervous energy to the heart; this is to be effected by tonics, gentle stimu-

lants, and nervines. To regulate the heart's action, as well as to relieve præcordial distress, the same means may be employed as named in the preceding variety. *Nux Vomica*, Citrate of *Strychnia* and Iron, *Aletris*, and *Cimicifuga*, form very excellent tonics; while *Gelseminum*, *Kalmia*, *Veratrum*, etc., are useful to diminish the palpitations. In many cases, I have derived much advantage from the following: Take of Sulphate of Quinia one drachm; Elixir of Vitrol three fluidrachms; mix, dissolve, and add, Tincture of Black Cohosh two and a half fluidounces; Tincture of Sheep Laurel ten fluidrachms, Tincture of Aconite three fluidrachms; mix. The dose is from twelve to thirty drops in a little water, to be repeated three times a day. In other instances, the Fluid Extract of Sumbul in doses of fifteen or twenty drops, will prove efficacious. The Tincture of Cactus has been found an admirable remedy in both the preceding varieties of cardiac palpitation. Anemia will require ferruginous tonics, and, in some cases, preparations of Manganese. When a burning sensation is complained of around the cardiac region, the following counter-irritant may be applied two or three times a day, on the surface over the affected part, viz.: Take Rect. Oil of Amber two fluidounces, Croton Oil half a fluidrachm; mix.

The skin, bowels, and kidneys, should be maintained in as normal a condition as possible; the diet must be nutritious, but properly regulated; and moderate exercise be taken daily, if the patient's condition will permit. When there is pain or tenderness on pressure along the spinal column or in the suboccipital region, counter-irritants must be applied over these painful points.

DIMINISHED ACTION OF THE HEART.

I do not here refer to the feeble action which occurs during the presence of organic cardiac lesion, but to that which is met with when there is no apparent structural change of the heart. The predisposing *causes* of this affection are, anemia, and a lack of proper nerve force, especially in the heart.

The principal *symptom* is syncope. But there may be premonitory symptoms, as, nausea, epigastric faintness, disturbed condition of vision and hearing, ringing in the ears, mental confusion, paleness of countenance, great muscular prostration, dilated pupils, diminished or suspended breathing, and eventually, syncope, which may last for a few seconds or even minutes, before recovery and a gradual return to consciousness occurs. During the syncope, the

cardiac impulse is greatly diminished, as well as the normal sounds, and sometimes these are hardly, if at all, distinguishable; the pulse at the wrist can not be felt, though that in the carotids beats feebly.

The exciting causes of the syncope are, principally, those that exert a depressing influence upon the vital powers, as, the use of tobacco, antimony, aconite, colchicum, arsenic, digitalis, oxalic acid, etc.; a great susceptibility or irritability of the heart; excessive galvanic stimulus applied to the roots of the spinal accessory nerve, to the first four cervical nerves, and to the cardiac sympathetic filaments; injuries to the brain, or other organs; extreme susceptibility to certain sounds, odors, or sights; prolonged stay in the warm bath; indigestible food; intense emotions; crowded rooms in which the blood becomes imperfectly oxygenized; profuse discharges; the introduction of a bougie into the urethra; fetal movements, etc. Although any one of these causes may induce syncope, yet it is more often occasioned by a combination of several of them.

As syncope is the principal symptom in the affection under consideration, we may form our *diagnosis* of it by observing that during the syncope, the surface is pale without any lividity; the pulse at the wrist can not be felt; and the beating of the heart can not be heard, or, at all events, very feebly and indistinctly. More or less weakness of the heart's force, and of the pulse, will be present during the patient's natural state.

In those cases where there is a constant feeble action of the heart, *without* syncope, there will be shortness of breath, coldness of the extremities, languor, indisposition to exercise, lowness of spirits, deranged appetite, œdematous swellings of the ankles, constipation, etc. The impulse of the heart will be feeble; the diastolic sound will frequently be reduplicated; and the slightest exertion or excitement may occasion a paroxysm of palpitation.

The *prognosis* as a general rule is not unfavorable; and patients recover from the syncope without any injurious results. Syncope in cases associated with, or due to anemia, has sometimes proved fatal; also, when excited by gastric irritability, or indigestible substances in the stomach. But, in all cases, the condition of the heart should be carefully examined, for in subjects of middle age especially, a diminished action of the heart is very apt to accompany some serious organic lesion.

The *treatment* for diminished action of the heart will be the adoption of such measures as will remove any exciting cause or causes, and restore power to the nervous system. Quinia, Cimici-

fuga, and Aletris will be found excellent agents for the latter purpose, conjoined with daily frictions over the surface of the body, and a proper attention to the skin, kidneys, and bowels, and to the diet. Iron is seldom required unless in cases of anemia, in which the Elixir of Iron and Cinchona, or, as a substitute, the preparation containing soluble Pyrophosphate of Iron, named under Chronic Peritonitis, will be found the best preparation. Galvanism must be made use of, as it is apt to improve the enfeebled condition of the heart, or, Pulvermacher's Galvanic Belts may be advantageously worn by the patient. Moderate exercise will often be useful. If the urine constantly gives an abnormal deposit of phosphates, the Compound Infusion of Trailing Arbutus, the Fluid Extract of Hydrangea, or, the Compound Balsam of Sulphur may be given, in conjunction with the Hypophosphite of Lime. Among female patients attention must be paid to the state of the menstrual function.—When an attack of syncope comes on, it must be treated in the usual manner; it is unnecessary here to dwell upon the various methods to be pursued.

ANGINA PECTORIS,

Also called Breast-pang, Spasm of the Heart, Suffocative Breast-pang, and Neuralgia of the Heart. The pathology of this disease is not satisfactorily determined. It has been variously ascribed to ossification of the coronary arteries, to valvular disease, to poly-pous formations, to spasm of the diaphragm, fatty accumulation, cardiac spasm, to an impediment to the coronary circulation, or, to some derangement or abnormal condition of the *par vagum* system of nerves, etc. From the fact that nearly all of the above-supposed causes are present in a majority of cases without any symptoms of angina pectoris, and that remedies addressed to the nervous system appear to exert more favorable influences upon the disease than any others, the prevailing opinion among medical men of the present day is, that angina pectoris is a nervous affection, and may exist with or without organic cardiac lesion. Among those lesions which are met with in cases of angina pectoris, that of fatty degeneration is by far the most common.

The *causes* of angina pectoris are not well understood; irritation of the *par vagum* at its origin in the medulla oblongata, in its trunk, or in its visceral extremities, appears to be a predisposing cause, as well as a gouty, rheumatic, or apoplectic tendency. The immediate or exciting causes are rapid walking or running up

stairs or up hill; muscular exertion; indigestible food; strong mental emotions; and whatever excites an augmented action of the heart. Males are much more subject to the affection than females, and especially those who are habitually addicted to the pleasures of the table, the sedentary, and the corpulent. It is more frequently met with after the fortieth year of age, when it is almost certain to be associated with some organic affection of the heart; that which is occasionally met with among children and in early manhood, may be considered a pure neuralgia without any cardiac lesion.

The *symptoms* of angina pectoris are a sudden attack of most intense pain in the region of the heart, described as lancinating, gnawing, cramp-like., etc., which shoots through the chest to the spine, to the left side of the neck and occiput, and into the left shoulder and arm. Sometimes it may pass into both arms, and even into the left leg, involving the testes. This pain comes suddenly and goes suddenly, and is always accompanied with a sense of impending suffocation, great anxiety, and a feeling of approaching death. During the paroxysm, which may last a few seconds or a few minutes, the most intense anguish is marked upon the patient's general appearance; his face is pale, and his extremities cold, with cold, clammy perspiration. If he recovers, he experiences a sense of relief, with a feeling of more or less exhaustion. These symptoms recur in paroxysms, and at uncertain intervals, and will vary much in their severity, the intervals between the paroxysms usually becoming shorter and shorter, until the patient dies in one of them. The death may be sudden, occurring with the paroxysm; or, it may take place gradually, with labored respiration, tetanic or clonic spasms, insensibility, and dissolution.

The *diagnosis* of this affection is not difficult. The first attack is generally experienced after some unusual exertion, as, walking up a hill, ascending a flight of stairs, rapid walking after a full meal, etc., and the pain is less severe and of less duration than subsequently. After a more or less considerable interval a second paroxysm occurs, and as the case progresses, the pain becomes more and more severe, the intervals between the paroxysms become shorter and shorter, and these are finally induced by very slight causes, as, mental emotions, walking, riding, coughing, sneezing, straining at stool, overeating, sexual excitement, etc. In many instances, the paroxysms are preceded by yawning and a sensation of heat in the chest, and occasionally a paroxysm occurs as the patient drops off to sleep.—During the paroxysm the patient can take a full inspiration, but as this augments the severity of the

pain, he almost always compresses his chest, and refrains from any kind of movement; the functions of the brain remain undisturbed; and, unless there be some co-existing cardiac lesion, the impulse and sounds of the heart will be normal, without murmur, and the pulse will not necessarily be affected, or, to a very small amount at the farthest. A murmur, or disturbance of the heart's rhythm is indicative of the presence of organic disease. However, when the disease is chronic, we will very frequently find the pulse irregular, and intermitting, and there will be more or less cardiac palpitations.

The *prognosis* is more favorable when the paroxysms occur previously to the fortieth year of age, or rather, when there is no organic change of the heart, a change which is seldom met with in early manhood; and unfavorable after this age, as the disease is then very apt to be associated with some organic affection. If, with the angina, there is a lividity of the face, with dyspnoea, the heart is structurally affected. But it must be remembered that, whether angina be co-existent with an organic lesion or not, a person who has once experienced an attack of it is ever after liable, at any time, to a sudden and fatal recurrence.—In all cases, the practitioner should make a careful examination of the condition of the heart, to determine any co-existing lesions of this organ. Unfortunately, the most common lesions observed in connection with angina, viz.: fatty degeneration and ossification of the coronary arteries, are very difficult to diagnose with any degree of certainty; and, indeed, in many instances, their diagnosis is impossible.

Post-mortem examination reveals no special appearances in the tissues of the heart indicative of angina pectoris. There may be no morbid lesions whatever of this organ; or, what is still more common, we may find more or less structural changes of the heart, its orifices, or of its arteries. And although these changes may dispose more readily to angina, and render a fatal result inevitable, they can not be considered as necessary or invariable concomitants of the disease. And if any information regarding the cause of angina can be had at all from the anatomical conditions more frequently observed, it seems to me, to be that the disease is principally associated with, or dependent upon, a deficient nervous power in connection with a defective nutrition of the heart.

The *treatment* of angina pectoris may be divided into that required during the paroxysm, and that during the intervals. In the paroxysm, stimulants and antispasmodics must be given, and probably the most effective one among them is the Compound Tincture of Virginia Snakeroot, a teaspoonful or two of which should be adminis-

tered at once in a little water, repeating this dose every few minutes during the continuance or recurrence of the fit. Other preparations, however, have been used with success, as, equal parts of Ether, Laudanum, and Tincture of Castor, in teaspoonful doses; or, Ammoniated Tincture of Castor; or, the Compound Cajuput Mixture. In addition to these, dry cupping, or firing, should be freely applied along the chest, over the region of the heart, and along the cervical and dorsal portion of the spinal column; the patient should be kept perfectly quiet, and active frictions, with stimulating mixtures, should be applied to the extremities, to aid in recovering the accustomed action of the heart. Slight electro-magnetic shocks may also be passed through the direction of the heart; but great caution is required in the employment of electricity or galvanism, using only the gentlest amount of this kind of stimulus, because overexcitement or exhaustion of nerves and muscles by this agent serves only to enfeeble them to a still greater degree. If it can be obtained readily, Oxygen may be inhaled to obviate the danger from an insufficiently aerated blood. Should the patient faint, Ether, or Spirits of Ammonia may be sprinkled on the face, neck, and breast.

As soon after a recovery from the paroxysm as possible, a mild cathartic may be given to remove any accumulation in the bowels, and to act as a derivative; but if the face be pale and bloodless, this should be dispensed with. If the paroxysm occurs shortly after a meal, an emetic should be administered as promptly as possible.

The treatment during the intervals is the most important, as by it we are to cure the disease, or at least to prolong the intervals between the paroxysms, as well as to check the tendency to attacks from minor causes. To do this effectually, the general health of the patient must be carefully inquired into, and if it be found that he is laboring under gout, rheumatism, structural lesion of the heart, etc., these must be combated by their appropriate treatment.

The bowels should be kept regular daily; the surface of the body be frequently bathed with a weak alkaline solution; and the kidneys be kept in a state of healthful activity. Internally, the Compound Tincture of High Cranberry, in conjunction with the Compound Pills of Black Cohosh, will be found the best agents to lessen nervous irritability and give tone to the nervous system. The Compound Pills of Hyoscyamus, and, in some instances, the Compound Pills of Aconite will be found serviceable. Acidity of stomach, when present, is best removed by Carbonate of Ammonia. In all cases, active counter-irritation should be alternately applied over the region of the heart, and along the cervical and dorsal regions of the spinal column. All sources of irritation, mental inquietude, and

sudden gusts of passion, should be vigilantly guarded against; moderate exercise in the open air, of a passive character will be useful, and in ascending a flight of stairs or other ascent, the utmost care and deliberation must be taken. The diet should be nutritious, but of a simple character, easy of digestion, and be thoroughly masticated. All indigestible food should be prohibited, as well as whatever disagrees with the stomach; late suppers, as well as full meals at any time, must positively be avoided. Proper attention should also be paid to clothing, sleeping, etc.

One severe case of angina pectoris I treated successfully by attentions to the bowels, skin, kidneys, and diet, together with the internal use of the following: 1. Take of Iodide of Ammonium one ounce, Water one pint and a half; mix. The dose was a teaspoonful, repeated three times a day. 2. Take of Sulphate of Quinia one drachm, Elixir of Vitriol three fluidrachms; mix, dissolve, and add Tincture of Black Cohosh two and a half fluidounces, Tincture of Sheep Laurel ten fluidrachms, Tincture of Aconite three fluidrachms; mix, and give from twelve to thirty drops in a little water, repeating it three times daily. To relieve an intense burning pain in the right side of the chest, the following liniment was applied twice a day: Take of Rectified Oil of Amber one fluidounce, Croton Oil fifteen minims; mix.

CONSTITUTIONAL DISEASES.

UNDER this head will be embraced, at this part of the work, those diseases which can not be properly arranged in any of the other divisions herein given, and which, although manifesting themselves at some particular part or organ of the body, are generally supposed to be due to some morbid condition of the blood, or of the capillary vessels, or to some peculiar virus or taint, or other depraved condition of the fluids. A supposition, indeed, which may, in my opinion, be safely entertained with regard to the major part of chronic diseases. Some of the diseases more properly belong to the department of surgery, but as they are frequently brought before the chronist for treatment, I have judged it best to make a brief reference to them.

SCROFULA.

Scrofula or King's-evil is a form of tuberculous disease that is very common; as ordinarily understood, it consists of an enlargement of lymphatic glands, which inflame, suppurate, and give rise to ulcers discharging a white, curdy matter, and which are often very troublesome to heal. Tubercular disease, or tuberculosis, is a morbid condition resulting from mal-nutrition of certain tissues, in which there is a tendency to the local deposition and accumulation of an abnormal substance termed "tubercle." This deposit usually occurs at certain points, or within certain organs, which, from exposures, hereditary influences, or other causes, have had their vitality diminished, and are, consequently, more liable to assume this form of disease. Tuberculosis manifests itself in many parts of the system, and is named, according to the parts attacked, scrofula, white swelling, hip disease, tubercular phthisis, rickets, lepra, bronchocele, etc.—Probably about one-fifth of the human family are affected with scrofula; of which number about one-half perish in infancy and childhood; and but a small proportion of the remainder arrive

at adult age. In those who are free from it, it may be produced by the vices and follies of men.

The *causes* of scrofula are not definitely known ; it appears, however, to be due to an insufficient nutrition of the system, or of certain tissues, in consequence of which there is a deficient amount of vitality. It is well known that in scrofula the blood globules are fewer in number than in the normal state, are lighter colored, and often of irregular form ; there is also a deficiency of fibrin, and the blood slowly coagulates, giving rise to a soft and diffuent clot. The tubercular matter itself, when examined under the microscope, presents numerous minute granular bodies, irregular exudation corpuscles, a considerable quantity of oil globules, some albuminous shreds, disintegrated tissue, and, frequently, pus. The addition of boiling ether will remove the oily matter ; and of acetic acid will render a greater number of corpuscles visible.

The peculiar condition of constitution favorable to the development of scrofula may be originally produced by various causes. It may be transmitted from generation to generation, not manifesting itself in one generation of a family, while severely afflicting another ; yet it is not invariably the case, that children born of scrofulous parents are affected with scrofulous diseases ; for often but one child is affected, while the rest of the children, to all appearance, present no symptoms of it whatever. One of the most important points in the selection of a husband or wife, should be, that he or she shall be free from the scrofulous disposition, and thus secure one great means of not generating scrofulous children.*

* A medical writer most justly observes,—“The end of marriage is domestic happiness, and the procreation of healthy children; and the former depends much upon the latter. The law is very particular about the forms of marriage, *but very indifferent about the results.* Rational marriages must rest with the parties themselves. Ignorance of the laws of constitutional health is one great cause of irrational marriages. The great motives to marriage are rank, property, fancy ; to these should be added, morals, intellect, health, which are more important for happiness. The moralist has hitherto been too little of a physiologist. Physiology is the basis of morals as well as of health. The educator should be a physiologist as well as a moralist. It is only by the union of the two that the young can be judiciously trained, and prepared for real life. However persons may despise physiological warnings, before marriage, they are too sensible of their value afterward. Constitutional diseases not only produce unhealthy children, but often also disgust, aversion, and misery between the parties themselves. Marriage will not strengthen a weak constitution as some suppose, but will debilitate it still more. It is a common observation of females, ‘I have never been well since I married.’ Child-bearing and nursing demand more than a delicate and tainted constitution can bear. The strength gives way under the heat and burden of the day.”

As a general rule, when adults are attacked with serofula, tubercles at the same time exist in the lungs. Again, serofula is often present among persons whose ancestors, as far as can be ascertained, were perfectly free from it; this fate is especially reserved for the children of those who marry after having abused their youthful powers, or exhausted their nervous energies by indulging too freely in venereal pleasures,—and is frequently met with among the offspring of those who have enfeebled the reproductive organs by masturbation, by frequent copulation during pregnancy, as well as of those parents who bear a blood relationship to each other, as, cousins, uncle and niece, etc. Children of a mother, and particularly of a father far advanced in years, often bring into the world a disposition to serofula, which will be developed at an early period, and often under the slightest exciting causes. Syphilis is also an undoubted cause of serofula; as well as premature marriage. Indeed, anything which will produce a defective vitality of the system, may be considered a cause of serofula, if an exposure to it be persisted in for a sufficient period, or it be associated with other depressing circumstances. In this manner, one or several of the exciting causes of the disease may develop it in a system previously free from the slightest tendency to it.

The late Prof. W. Byrd Powell asserted that serofula is the rule and not the exception among the offspring of those parents who are free from serofula themselves, but with whom there is a marked incompatibility of temperament and constitution; and he sustains his assertion by the strongest possible evidence. His views are certainly deserving the closest attention of physiologists.

The exciting causes of serofula are, artificial suckling; improper food; a free use of vegetable diet with little or no animal; the use of farinaceous preparations imperfectly cooked; too much succulent diet; excessive use of pork or fat meats; excessive use of acidulous articles; impure atmosphere; want of exercise; uncleanness; exposure to too great a degree of heat; too early mental application; improper use of opium, mercurials, etc.; venesections; and a too early exercise of the sexual organs. Among those who are predisposed to it, it is frequently excited into action by certain diseases, as measles, small-pox, scarlatina, vaccination, etc., following as a sequel to the diseases. One great exciting cause of the disease, and perhaps a powerful predisposing cause, also, is a neglect of the skin; indeed, one writer considers tubercle to be "the solid matter of the cutaneous excretion, especially of the sebaceous

follicles. This secretion not being expelled by the natural emunctories, is retained in the blood, until, in the attempt to eliminate it through an unnatural channel, it is deposited in some other excretory organ, where its fluid matter being absorbed it becomes a tubercle." That there is some truth in this opinion may be granted—still, I have found scrofula in persons who, as well as their parents, made a proper attention to the various excretions of the body daily, a matter of duty.

The attacks of scrofula are much influenced by climate, and the seasons of the year; prevailing more extensively in temperate latitudes, where the climate is variable, and cool or moist, commencing generally in the winter or spring, and disappearing, or considerably amending in summer or autumn.

Authors generally describe certain *external appearances* in the general contour of the person; in the eyes, lips, nose, countenance, or complexion, by which, they say, scrofulous individuals may be distinguished from those who are non-scrofulous. That there are certain appearances which are frequently observed among persons who are supposed to have a predisposition to scrofula, is undoubtedly true; yet there are no certain signs upon which an implicit reliance can be placed. Even among those in whom there is an undoubted scrofulous taint, with enlargement of the subcutaneous ganglia, we find their external signs to present the greatest variety; thus, the complexion as well as the hair, will be observed in some, light, in others, dark; the lips either symmetrical, the lower one enlarged, or else the upper one; the *alæ nasi* may be somewhat contracted, or expanded; the countenance may be pale or ruddy; the constitution may present the appearance of being delicate or robust; the skin may be dry and hard, exhaling a greasy odor, or a fetid and acid perspiration; the abdomen may or may not be tumid; the eyes may be heavy, languid, inexpressive, or animated and sparkling. But, in cases where there is no tumefaction of the subcutaneous glands the above signs are uncertain, inconstant, and unsatisfactory. Indeed, the glands may be enlarged, and no scrofulous deposition exist in them, as is often observed from irritation; yet, when no irritation exists, and the glands are swollen, the evidence in favor of a scrofulous constitution is much stronger than that from the external signs above referred to. A medical writer observes truly: "The most certain evidence of the existence of a scrofulous disease, is afforded by the production of a soft, brittle, unorganized matter, resembling curd or new cheese, which is found mixed with the contents of abscesses, or deposited in rounded masses of different degrees of firmness, and varying in bulk from

the size of a millet seed to that of a hen's egg; sometimes it is enclosed in cysts, and occasionally it is diffused, as if by infiltration, through the natural texture of the part. To the rounded masses of this substance, the name of tubercle has been assigned, and the substance itself has been named tuberculous matter." Yet, notwithstanding this is the most certain evidence, and one of the most obvious and leading effects of scrofula, our ideas of the disease should not be improperly confined to it. It is but one effect or disease, among many, which arises from a common constitution. Scrofula undoubtedly produces certain diseases, the peculiar characters and symptoms of which depend upon the organs or tissues affected, and their offices and functions, as, tumors of the brain, hydrocephalus, epilepsy, insanity, hysteria, deafness, otorrhea, conjunctivitis, lippitudo, myopia from staphyloma posterior, ozæna, coryza, heart diseases, consumption, uterine and ovarian diseases, dyspepsia, nervous debility, lupus, cutaneous diseases, etc. It also exerts a modifying effect upon other diseases which occur in a scrofulous system, as, hooping-cough, scarlatina, measles, small-pox, syphilis, gonorrhea, etc., rendering them less amenable to treatment than if they had affected a system free from scrofula, or even rendering them positively incurable, or fatal.

Children who are evidently scrofulous, more generally have a soft, fine skin, waxy, delicate complexion, tumid abdomen, enlarged joints, blue eyes, long eyelashes, large, prominent forehead, and an appearance of freshness and plumpness which is due to hypertrophy of the cellular membrane, and is of a morbid and delusive character. On the other hand, scrofulous children will often present a coarse, pale skin, perhaps covered with numerous fine hairs, a dark complexion, dark eyes, no enlargement of the abdomen nor of the joints, but a great susceptibility to morbid conditions of the mucous membranes, as, of the eye, ear, nose, mouth, stomach, and bowels, and even in the mucous membrane of the genito-urinary system. Some are born with the disease fully formed; others are affected soon after birth with ophthalmia, though this may be present in non-scrofulous cases; while again, others have glandular enlargements, or present certain cutaneous eruptions, ulcerations, etc. With many children, the evidences or effects of malnutrition, imperfect assimilation, and enfeebled circulation and nervous energy, are so well marked, that the scrofulous taint is readily recognized.

The *symptoms* of scrofula vary somewhat according to the parts or tissues affected, some of which will be described hereafter under

the several names given to them, as, Consumption, White Swelling, etc. At this place I will confine my description to those symptoms which accompany the enlargement of the subcutaneous glands, and to which the name of Scrofula is more commonly applied.

The first, most common, and distinctive symptom of scrofula, is an enlargement of the glands referred to, especially those about the neck, forming what are termed "tumors," or "kernels," and which may remain in an indolent condition for a long time, neither increasing in size, nor diminishing (except under proper treatment, diet, or regimen, or under the re-invigorated powers of the system, and from these circumstances, they do sometimes disappear), and occasioning no pain or other unpleasant symptoms. After a longer or shorter time, and especially under the influence of one or more exciting causes, the affected glands, or at least some of them continue to enlarge, and a low form of inflammation is developed at the same time, with more or less pain, and, as the disease progresses, the pain and inflammation become more severe, the enlargement augments rapidly, the parts become hot, painful on pressure, and the neighboring tissues also become swollen, hard, and partake more or less of the inflammatory action. After a longer or shorter period, suppuration occurs, the matter formed burrows its way to the surface, occasioning an abscess or ulcer, from which is discharged a thin, ichorous pus, mixed with curdy or cheese-like flakes. This pus may be discharged from one orifice; frequently from several small ones, and when this is the case the sinuses eventually coalesce, and give rise to indolent ulcers with jagged and uneven margins, which heal slowly, leaving unsightly scars. Other tumors form in turn, pass through similar changes, and in this way the disease may be perpetuated for years until it becomes cured, or the system becomes destroyed by it. This pus can not produce scrofula in a healthy individual, even by inoculation.

The period of suppuration will be found to vary very much, in some cases forming an abscess in ten or twelve days, in others, not until several weeks have passed. The abscess may heal in a short time, but more frequently it will remain in an indolent condition, manifesting no tendency to heal, unless under the influence of local applications. It is rarely the case that the pus discharged is laudable.—In many instances, the enlargement and suppuration of the the scrofulous tumor progresses without any of the inflammatory symptoms.

During the inflammatory process there may be general febrile

symptoms, or symptoms of irritation, followed by rigors during the suppurative period; and these symptoms will be more or less severe, according to the severity of the scrofulous affection and the general tone of the system. Paleness of the surface, languor, debility, derangement of the secretory and excretory functions, impaired appetite and digestive powers, hectic fever, and night sweats, are commonly present as evidences of the degree of constitutional disturbance.

Hufeland observes that at first the swellings are "small, movable under the finger, elastic, not painful, and without any change of color in the skin. Those on the sides and back part of the neck are commonly the first to feel the influence of the scrofulous taint; the examination of these parts is, therefore, of the utmost importance in establishing the diagnosis. After these, and even sometimes before, the glands of the armpits begin to swell in their turn, then comes those of the groin, and, in some instances, those of the whole body. Their size and consistence gradually augment, engorgement of the surrounding parts take place, and thus they lose their mobility. It is uncommon for a single gland to be affected; the contagion ordinarily extends to several; indeed they are often confounded together, and form an enormous tumor, or become united without being confounded, so as to resemble a sort of chain. At length, when the disease has reached a certain height, the lymphatic vessels themselves are engorged, and feel like catgut. . . . These tumors may remain in the same state during several years; but at the commencement they are variable, appearing and disappearing alternately. In proportion as the scrofulous taint increases, the glandular tumors become harder and less movable. In some cases they remain cold and indolent; in others, the skin above them reddens, pain is felt in the center of the gland, inflammation slowly takes place, and suppuration follows; but the pus is always of a bad quality."

The *prognosis* of scrofula depends much upon circumstances; the more vigor and strength there is in the constitution the more favorable will it be, and more especially so when the disposition to the disease is but slight; and, in cases where there is only a slight tendency to scrofula, with a strong constitution, the chances of cure are much greater than in the reverse conditions. A highly scrofulous constitution is rarely curable, unless treatment be commenced in childhood, and be persevered in for several years under favorable circumstances. In itself, scrofula can not be considered a mortal affection, but it may, and too commonly does, become so,

either by attacking organs that are essential to life, or, in effecting extensive disorganizations.

The *treatment* of scrofula is divided into therapeutical and hygienical. The therapeutical is subdivided into constitutional and local. The constitutional treatment consists in the administration of alteratives internally, which improve the condition of the blood and aid in the gradual removal of that peculiar morbid state of the system upon which the disease depends. The agent upon which I place the greatest reliance is the Compound Syrup of Yellow Dock, to which sufficient Iodide of Ammonium is added, so that a child ten years old may take with each dose, one grain of this salt; and, in most instances, I likewise add from one-sixteenth to one-eighth part of the saturated Tincture of Cimicifuga; the dose of the fluid mixture being a teaspoonful three or four times a day. Other agents may be used, as, Iodide of Potassium, Iodine Pills, Bromide of Potassium, Bromide of Ammonium, Compound Sarsaparilla Syrup, the preparation containing soluble Pyrophosphate of Iron, named in the treatment of Chronic Peritonitis, etc., which have frequently been found exceedingly beneficial. In some cases, the following preparation will have a most decided curative influence, viz.: Take of Chlorate of Potassa two drachms, Hydrochloric Acid forty minims, Distilled Water one and a half fluid-ounces; mix. The dose is a teaspoonful three times a day, for an adult. In all cases of scrofula, those alteratives will be found the most efficient that exercise an influence on the kidneys, increasing the quantity of urine and improving its quality.

It will sometimes be the case that no effect whatever will be exerted upon the scrofulous glands or abscesses, although a persistent constitutional treatment of several months has been pursued. I have met with considerable success in such obstinate cases, by arousing the susceptibility of the glandular system, by means of agents continued until a salivation has been effected. The agents employed are, a mixture of equal parts of Blue Flag, Mandrake, and Prickly-ash Bark, given in doses of two, three, five, or ten grains every two or three hours, (not to act upon the bowels), and continued until salivation is produced. Or, doses of from one-eighth of a grain to a grain of a mixture of equal parts of Iridin, Podophyllin, and Xanthoxylin, may be substituted for the above. The salivation caused by this preparation is entirely different from that resulting from the employment of mercurials, and is entirely free from danger;—there are many other obstinate forms of disease, in which this effect will be followed by the most happy results. After the salivation has been produced, the ordi-

nary constitutional treatment may be pursued. This action may be repeated again and again, if the obstinacy of the disease should require it.

It may be proper to state that Protein has been recommended for scrofulous children, in doses of three grains for a child five years old, gradually increased to five grains, to be taken three times a day in sweetened water; and if the stomach be acid, it may be combined with two or three grains of dried Bicarbonate of Soda added to each dose. Oxide of Manganese, in doses of one-seventh to three-fourths of a grain for a dose, has also been highly spoken of as a remedy for young scrofulous children.

Acidity of stomach is frequently present in scrofulous affections, and should always be removed or neutralized by alkaline preparations, or by absorbents; otherwise, it will interfere with the action of the alteratives. The articles which may be used against this symptom are Prepared Charcoal, Lime-water, Hypophosphite of Lime, or, if there be much gastric irritation, Bromide of Potassium.—In cases where the appetite is bad, with imperfect digestion and biliary secretion, and constipation, laxatives and tonics may be employed; the following forms an excellent preparation for this purpose: Take of Bromide of Potassium one hundred and sixty grains, Alcoholic Extract of Aletris forty grains, Podophyllin ten grains, Strychnia four grains, Extract of Yellow Dock, a sufficient quantity to form a pill mass; mix, and divide into one hundred and eighty pills, of which one is a dose for an adult, to be repeated three times a day. For children, the pills will require to be divided each into one-half or one-fourth, and then be rubbed up with some agreeable excipient or draught. Wine, ale, iron, or Elixir of Cinchona and Iron, may also be used to aid in giving tone to the digestive organs, when feeble. Great attention must always be bestowed upon the digestive organs in the treatment of scrofula.

When the patient is greatly debilitated, much benefit will be derived from wineglassful doses, repeated three times a day, of a preparation composed of pulverized Cinchona two ounces, soluble Pyrophosphate of Iron sixteen grains, Port Wine one pint. Or, the Citrate of Iron, or, Citrate of Iron with Strychnia, Bromide of Iron, Iodide of Iron, etc., may be employed, especially when an anæmic condition is likewise present. Cod Liver Oil will frequently prove very beneficial, either alone, with wine, or in conjunction with an infusion of some vegetable bitter tonic. The selection of the particular agent must be left to the judgment of the practitioner, for what may prove serviceable in one instance may fail in another.

The local treatment will depend considerably upon the condition of the affected parts; if the enlargement be free from inflammation and from any great tenderness, its resolution may be promoted by one of the following mixtures: 1. Dissolve Hydrochlorate of Ammonia half an ounce, in two fluidounces of Distilled Water, and then add to the solution two fluidounces of a saturated Tincture of Conium. Moisten a linen or cotton compress with this, and keep it constantly applied upon the swelling. 2. Take of Saturated Tinctures of Belladonna, and of Stramonium, and Glycerin, each, one fluidounce, Iodide of Ammonium one drachm; mix, and use same as the preceding. 3. Take of Bromine twelve minims, Distilled Water half a pint; mix, and use as above; or, a drachm or two of Bromide of Potassium may be added to this elegant lotion. 4. The Compound Plaster of Belladonna will prove useful in many cases. 5. Take of Iodide of Ammonium one drachm, Spermaceti Cerate one ounce; mix, and rub upon the part several times a day. 6. Galvanism applied to scrofulous enlargements frequently produces absorption, and, in many instances, when applied at a later period, hastens their suppuration. 7. Take of Iodide of Ammonium one drachm, dissolve it in Distilled Water one fluidrachm, and then add to it Alcohol six fluidrachms, Cologne one fluidrachm; to be employed in frictions two or three times a day.

I now make known for the first time a measure that I have employed in many cases of scrofulous enlargements with the most marked success; it consists in injecting into the parts around the swelling, every day or two, by means of a hypodermic syringe, a solution composed of Chloride of Gold and Soda four grains, Distilled Water one to four fluidounces; if too great a degree of irritation be produced, the quantity of the Gold salt must be lessened.— Sometimes a solution of Permanganate of Potassa will be found useful.

If much heat, redness, pain, and inflammation are present, these must be subdued by the application of fomentations or poultices; as, a fomentation of Stramonium and Wild Indigo Leaves; or of equal parts of Stramonium and Lobelia; or one of the following poultices,—equal parts of Cicuta Leaves and Elm Bark; pulverized Indian Turnip mixed with Warm Water; equal parts of pulverized Blue Flag Root, Poke Root, and Elm Bark; or, equal parts of pulverized Elm Bark and Bayberry Bark. Sometimes, fresh Poke Root, roasted in hot ashes until soft, mashed, and applied, will be found to answer an admirable purpose. Whichever fomentation or poultice is applied, it should be renewed every three or four hours. Not unfrequently, a few leeches applied at the commencement of

the inflammatory action, followed by cold applications, as, of Ice or Iced Water, will check the abnormal action and promote absorption; and, sometimes, this course may be pursued to prevent suppuration from being established,—great care must be taken, however, not to freeze the parts.

When suppuration has occurred, the earlier the pus is discharged the better; therefore, as soon as fluctuation distinctly proves the presence of fluid, with some attenuation of the skin, the abscess should be opened by the application of Caustic Potassa passed into the cavity of the suppurated tumor; this will give rise to less deformity than if the knife be used. However, when the pus is rather deeply situated, instead of waiting for it to pass toward the external surface, and at the same time burrow around and extend into the neighboring tissues, it will be better to use the lancet in order to promptly give exit to it, and the orifice thus made may subsequently be kept open by means of the Caustic Potassa, should it manifest a tendency to close. The orifice made by the lancet should be as small as possible, no longer in extent than is necessary for the passage of the pus. The pus should be allowed to flow out slowly, making no pressure to facilitate its exit; and at the same time, the abscess should be covered with one of the poultices hereafter named, in order to facilitate the progress of the suppuration.

When an ulcer or abscess has formed, and has been discharging for several weeks, the local treatment will be somewhat different from that of the preceding. As these abscesses are almost always of an indolent character, they must be washed or syringed daily, with a mixture of equal parts of Castile Soap-suds and Whisky, to cleanse them, followed by some sufficiently powerful stimulating preparation, as, a solution of Vegetable Caustic injected into the cavity; or, the powdered Caustic may be introduced on tents into the sinuses or openings; after which apply upon the ulcer, spread on some lint, the Ointment of Bayberry, Mayer's Ointment, or the Red Oxide of Lead Plaster. At night a poultice of equal parts of Elm Bark and Bayberry Bark may be applied, especially if some degree of inflammation be present. A very beneficial poultice for a scrofulous ulcer is made of equal parts of Frostweed, Figwort, and Wild Indigo Leaves. Whatever may be the dressing employed, it should be renewed and the ulcer be cleansed at least twice a day.

The hygienic treatment is fully as important as the therapeutical; indeed, an inattention to it will prevent the best remedial measures from being successful. The diet should be nourishing and easy of digestion, the patient eating full meals, but without offending or

overloading the stomach ; but acids, indigestible substances, fat or greasy articles, and especially fat or lean pork, must be avoided. Salt may be freely used ; it is very beneficial in this disease. The moderate use of wine, ale, porter, or even brandy is admissible and useful. Regular and moderate exercise in the open air, gradually increased, but never to cause fatigue, should be taken every day. The bowels, kidneys, and skin should be kept regular and in as normal a condition as possible, but they should never be enfeebled by over-stimulation. It is advisable to bathe the whole surface of the body and limbs, daily, with a mixture of Rain Water, Vinegar, each, half a pint, Whisky one gill, Sal Soda one drachm ; and friction with flannel or with the flesh-brush should be applied to the body and limbs, once or twice a week, each time exciting a gentle glow of heat. A Spirit Vapor Bath every three or four weeks will be found of much service in establishing a healthy condition of the skin and capillary organs, and will likewise aid very much in facilitating the cure. The clothing should be sufficiently warm and comfortable, and the hours of sleep should be properly regulated.

WHITE SWELLING.

White Swelling, Hydrarthrus, or Synovitis, is a very formidable and painful articular disease, which more frequently affects the knee-joint. It may be acute or chronic, but more commonly the latter. The term "white swelling" has been applied to the disease because, notwithstanding the inflammation and the enlargement of the joint, the color of the skin surrounding it remains natural, or pale and shining. Although other articulations may be affected with the disease under consideration, as, the ankle, wrist, elbow, finger, and toe joints, my remarks are especially intended for the knee affection.

The *causes* of chronic articular disease are various ; it may be induced by an exposure to cold, by blows, falls, sprains, or other violence ; it may result, likewise, from the employment of mercurials, or from syphilitic disease ; but the more frequent causes appear to be rheumatism and scrofula ; and those of a strumous or scrofulous constitution appear to be particularly liable to it, in which cases the disease assumes the characters of "tuberculosis."

The *symptoms* of chronic synovitis usually manifest themselves in a slow, insidious manner, frequently requiring months before the more advanced symptoms of the swelling are observed. At first an uneasiness is experienced in the joint, or a stiffness, which passes away after exercising the limb ; the joint will present a slight degree of swelling, which gradually increases. Slight pain is soon felt,

which, after a longer or shorter time, becomes very severe ; in many instances, pain will be the first symptom complained of. It often becomes so intense that the patient can not bear to move the limb : he does not place the sole of his foot firmly upon the ground, but merely touches it with his toes, while the knee-joint is kept constantly flexed. The central portion of the knee is, in most instances, apparently the part more especially affected, and if pressure be made upon this part, which will not exceed an area of six lines in diameter, the greatest pain will be produced. As the pain increases, so also does the swelling, and the skin presents a smooth, pale, glossy appearance, with enlarged veins running through it ; great heat is also present. The joint may continue in this state for months or years without any considerable change, or it may proceed rapidly to suppuration, and which is the more common result when the inflammatory action is severe. Eventually suppuration takes place, which is announced by more or less violent rigors, and this is more common in the scrofulous variety than in the others. A number of orifices are formed, through which the pus escapes ; and the ulcers may heal with or without other ones subsequently forming. The affected limb becomes wasted, and permanently flexed.

The constitution is very apt to sympathize with the local disease, particularly when this is severe ; there will be more or less febrile excitement, nervous irritability, derangement of the appetite and digestive organs, sleeplessness, and impairment of the excretory functions. The pulse becomes small and frequent, hectic fever manifests itself, with night sweats, and, frequently, an obstinate colliquative diarrhœa. Under the great constitutional irritation thus produced, the patient gradually emaciates, and finally dies.

There are three varieties of white swelling, termed *rheumatic synovitis*, *strumous synovitis*, and *syphilitic synovitis*.

Rheumatic synovitis may be due to an injury, exposure to cold, rheumatic or other acute inflammation, or to excess in diet. The disease may be attended from the commencement with the more active local and constitutional symptoms above referred to ; or, it may progress so gradually as to render it almost impossible to point out its commencing period. The affection is more common in early life, rarely being met with after the thirtieth year. The pain is generally more of a gnawing character, is less severe at night, and the accumulation of serous fluid in the synovial sac may be so great as to constitute a true dropsy of the joint, or *hydrarthrosis*. The disease may terminate favorably, or it may proceed to suppurative destruction of the joint, more especially in scrofulous systems.

Syphilitic synovitis is met with in persons laboring under the ter-

tiary form of syphilis, especially those who have had their constitutions enfeebled by mercurials and intemperance. Considerable synovial fluid is usually effused, and the pains are worse at night. The disease is generally attended with evidences of syphilitic taint in other parts of the system. This variety rarely terminates favorably, and particularly if it be associated with a scrofulous constitution.

Strumous synovitis, or tuberculosis of the knee-joint, and which is the variety to which I have more especial reference when speaking of treatment, is a very common affection among children, though occasionally met with among adults. The disease may assume an active character presenting the symptoms above described. When it is of a very chronic character we find the affected joint becoming gradually rounded and enlarged, the swelling being uniform, doughy, semi-elastic, or pulpy. The limb wastes, the joint is held in a bent position, and much pain is not experienced unless the limb be moved. The disease has a strong tendency to suppuration, and it is only as it advances toward, and through this stage that the symptoms of irritation and hectic-fever are manifested. The disease is very apt to implicate the bones of the part affected.

The *prognosis* in chronic synovitis, is not, as a general rule, very favorable, and particularly if the osseous parts are involved. At an early period, before much change in the structures of the joint has been effected, the disease may frequently be checked in its progress, and the joint be saved; at a later period, if we can arrest any further advance of the disease, the patient will be left with a deformed and ankylosed joint. If suppuration has occurred, and the constitution manifests great sympathetic irritation, the prognosis is unfavorable, especially if the system is highly scrofulous, with a tendency to tuberculous deposit in other parts.

A post-mortem investigation reveals only the various effects of the disease upon the several structures forming the joint, and not the disease itself. The soft tissues surrounding the joint are more or less thickened and contain fatty and plastic infiltrations; the cartilages of the joint are soft, inelastic, and dull, or disintegrated, or wholly destroyed; the synovial membrane will be thickened, rough, vascular in some parts, more or less removed, or it may be replaced by a gray or brownish pulpy substance, or by a viscid fatty deposit; the ligaments may likewise be inflamed, softened, or destroyed; the synovial fluid will be in increased amount, somewhat normal, viscid, or thin, yellow, and purulent, containing more or less fatty matter, or flakes of lymph, and sometimes, thick and grumous. If the bones are diseased, their articular extremities may be

expanded or enlarged, the osseous structure thin and expanded, and the cancellated cells occupied with a bloody and fatty serous fluid. Tuberculous or fatty matter may be deposited in the bones. Caries or necrosis may be present. These various conditions will differ according to the variety of the disease, its severity and its duration.

The *treatment* of white swelling is both constitutional and local. The former consists in the administration of such remedies as will remove any rheumatic, syphilitic, scrofulous, or other condition of the system, improve the blood, and give tone and energy to the nervous system; and the agents for these purposes are more especially referred to under the heads of Rheumatism, Constitutional Syphilis, Scrofula, etc. As to local treatment, if there is much inflammation and pain present, the joint should be exposed to the action of hot vapor arising from a decoction of equal parts of Stramonium, Lobelia, Hops, and Wormwood—covering the knee lightly so as to retain the steam; this may be repeated two or three times a day, if the case be very urgent. The whole of the knee should also be painted two or three times a day, with the following, or some similar preparation: Take of Extract of Belladonna one drachm, Alcohol two fluidrachms; rub the two articles well together, and then add to them Iodide of Ammonium three or four drachms, Glycerin one fluidounce. Or, the Compound Belladonna Plaster may be used. Recent Stramonium Leaves, bruised, and applied will also be found beneficial. If the inflammatory symptoms are severe and obstinate, in conjunction with the above measures, it may become necessary to apply leeches freely. It must be recollected, however, that unless the symptoms are acutely inflammatory, these local measures will seldom be of service in relieving the pain. I have derived considerable benefit in pain and inflammation, by hypodermic injections of Muriate of Morphia, in the vicinity of the affected parts, even when all other means had failed to give any relief.

The most important part of the local treatment, both in the more active and in the chronic conditions of the disease is, to keep the limb constantly in a state of rest, being very careful when applying the local measures, to preserve a perfectly immovable condition of the joint. And for this purpose, it may become necessary to place the limb in splints, so adapted as to keep the joint motionless, and at the same time effect an extension sufficient to prevent compression of the bones from muscular contraction. The starch bandage will, in some instances, be found to answer a much better purpose than splints.

In the chronic stage, or after the acute inflammatory symptoms

have been subdued, there is probably no application that will have so beneficial an influence upon the disease, as the Compound Tar Plaster, which should be allowed to keep up a discharge as long as possible. In some cases, it will require to be applied intermittently; and, in others, the patient will not be able to bear it at all, either from the soreness it produces, or because it develops inflammatory action which it is not desirable to have extend to the joint; in which cases, hypodermic injections of a solution of Chloride of Gold and Soda may be made daily, or every other day, in various parts around the swelling, into the more healthy tissue. About the thirtieth or fiftieth part of a grain of this salt, in solution, may be employed at one injection. If neither this, nor the Tar Plaster can be used, nor be borne by the patient, adhesive straps may be applied over the diseased part, provided there is no inflammatory action present, subjecting the part to as much pressure therefrom as the patient can endure, and without augmenting the pain. And these should be so arranged around the joint, as to admit of such fluid applications to the parts as the practitioner may desire, from time to time. Indeed, straps or bandages to the joint as firmly or as tightly as the patient can comfortably bear, should never be omitted in the chronic form of the disease, except when the Compound Tar Plaster is being employed. And should there at any time be a renewal of inflammation and pain, the same measures must be pursued to overcome them as advised above; omitting the other applications in the mean time.

A very useful preparation with which to paint the swollen joint, when straps or bandages are used, in the chronic stage, is the following: Take of Iodine one drachm, Iodide of Ammonium two drachms; Alcohol, or Glycerin, four fluidounces; mix, and dissolve the Iodine and Iodide. This may be applied, one, two, or three times a day, according to circumstances.

If suppuration ensues giving rise to the formation of abscess, this should be discharged as soon as practicable by an artificial opening; and the abscess should be washed or syringed once or twice a day with Castile Soap-suds, and immediately afterward with a solution of the Vegetable Caustic, as strong as can be borne; and any great amount of pain arising therefrom may be lessened by the use of the local vapor bath, or by anodyne fomentations. A weak solution of Permanganate of Potassa, injected, will frequently be of service; or, the treatment advised for scrofulous abscess may be pursued. This treatment should be faithfully persisted in as long as pieces of diseased bone are discharged, or as long as the ulceration continues.

An attention to the functions of the skin, bowels, and kidneys, are very necessary in this malady. And the diet should be the same as that recommended under Scrofula; sustaining the strength of the patient by tonics, should he become much enfeebled. This is a very troublesome disease, frequently requiring several months before any permanent benefit can be effected, and often proving intractable to any treatment; the above measures are the principal and more important ones to observe, but the disease may present itself in so many phases, and under so many circumstances, as often to require modifications and additions, which it is impossible to enter into here, not being within the scope of this work. However, these modifications, etc., may be readily and correctly made by any practitioner who is thoroughly posted in the general principles of Practice and Surgery.

HIP DISEASE.

Hip Disease, also named Coxalgia, Tuberculosis of the Hip Joint, is an affection more commonly occurring among scrofulous children under twelve years of age, though it may happen at any period of life, and among persons free from any scrofulous taint. Children from two to six years old are much more frequently attacked with it than at any other age. Both hip joints are seldom affected at the same time; and, as the disease advances, it sometimes becomes complicated with scrofulous disease in one or several other parts of the system.

The *causes* of hip disease are but imperfectly understood; the scrofulous taint is the predisposing cause. The exciting causes are, cold, dampness, residence in an impure atmosphere, improper diet, want of proper nourishment, profuse discharges, exhaustion from acute diseases, want of exercise, and, sometimes, severe injuries to the part from blows, falls, overexertion, etc. In many instances, the disease comes on spontaneously without any attributable cause.

The *symptoms* are often developed so obscurely and gradually as to mislead us relative to the true character of the affection; and, in some cases, many months may pass before our suspicions become aroused. At first, the patient complains of slight pain in the knee, but which does not interfere with the ordinary exercise and daily amusements. Ultimately this pain becomes more severe, is aggravated by any kind of motion, or exercise, and is worse at night. An examination of the knee will not detect any enlargement or redness of this joint, and pressure will not occasion pain in any of its parts. After a longer or shorter time the pain will be

felt in the hip joint, along the anterior, lateral, or posterior parts of the leg, in the heel, in the ankle, etc., often shifting from one of these parts to another. The pain will vary in severity from time to time; it is not constant, the patient often passing several hours free from it.—Sometimes the pain will be first observed in the hip joint; and, again, in both the hip and knee simultaneously. It may also be severe from the first, and the consecutive symptoms may progress more rapidly than is named here.

If an examination be made about the time the pain affects the hip, the leg on the affected side will be found from half an inch to two inches longer than the opposite one, and which will be more readily detected upon placing the patient in an erect position, when the knee will likewise be found more or less flexed, and the foot turned somewhat inward. If the limb be seized in both hands and pressed upward, as if to carry the head of the femur farther upward into the acetabulum, at the same time slightly rotating the limb, pain will be experienced in the hip joint. Pain will also be produced or augmented by percussing the knee when the limb is flexed at this joint, and also by pressing upon the region of the glutei muscles. The nates will generally be somewhat flattened.

As the disease continues to progress the general health becomes impaired; there will be a wasting of the muscles of the affected limb, together with spasmodic twitchings or jerkings; disturbed sleep; annoying or frightful dreams; startings from sleep in a state of mental confusion; deranged appetite; tendency to constipation; scanty and high-colored urine; febrile symptoms; peevishness; irritability; emaciation; profuse sweats, etc. These symptoms are not always present; but there is almost always a wakefulness or disturbed sleep, which produces its influences upon the constitution in a greater or less degree.

After more or less suffering, suppuration occurs, as, indicated by augmented pain, throbbing, rigors, high fever, profuse sweats, œdema of the subcutaneous tissue, and an inability to move the limb in the slightest degree, at least without experiencing the most intense pain. Occasionally, instances may be met with in which the more severe symptoms of suppuration will be wanting. The pus increasing in amount, gradually advances toward the surface, at some point of which it is discharged. It more commonly forms an opening behind the joint under the gluteal muscles, though other points are frequently met with, as, in the groin, in the posterior and superior part of the thigh, a little inferior to the great trochanter, etc. Not unfrequently the pus will be discharged from several orifices at different points; and the sinuses will be long and

tortuous, with false membrane lining their walls, more especially in long-standing cases.—The pus discharged is less consistent than ordinary pus, has a greenish tinge, and contains small granular bodies, minute sanguineous clots, sometimes cartilaginous or osseous debris, and is often very fetid. With the exit of the pus, the pain becomes greatly relieved, though the usual hectic symptoms accompanying profuse and long-continued discharges are always present, being more or less severe according to the character of the discharge as to quantity and quality.—After the first-formed pus has been discharged, that which follows is usually of an ichorous character, and sometimes tinged with blood.

At this period of the disease the limb of the affected side will be found greatly emaciated; the thigh will be more or less flexed toward the abdomen, and inclining toward the opposite side; the limb will now be shorter than its fellow; and, in the erect posture, the toes and ball of the foot only will rest upon the ground, while the heel will be raised more or less above it; more frequently the foot will incline inwardly,—occasionally, outwardly. The knee will also be more or less bent, the leg being flexed toward the thigh.

The *diagnosis* of hip disease, as a general rule, may be readily determined by a careful examination of the case. However, it has sometimes been mistaken for psoas abscess, rheumatism of the hip joint, or an injury, as, a sprain.—In *psoas abscess* there is hardly any pain in the knee, the pain being located in the lumbar region, and is greatly augmented when the patient stands erect, or extends the leg of the affected side; coughing, sneezing, etc., produces an impulse in the swelling which may be distinctly recognized; besides which, there is no elongation or shortening of the limb, and the disease is seldom met with until after adult age. In hip disease, the pain is in the knee and hip, the patient has a limping gait, the limb, at first, is elongated, afterward shortened, no impulse can be perceived in the swelling upon coughing, etc.; and the disease is more common prior to ten or twelve years of age. Psoas abscess is generally located above Poupart's ligament, and no pain is produced upon pressing the limb upward and slightly rotating it.

Rheumatism and *Sprain* may be distinguished by the history of the case, the absence of pain in the knee, the absence of pain upon pressing the limb upward and rotating it, the absence of stiffness in the hip after exercise, the want of alteration in the shape and position of the limb, the absence of constitutional disturbance, and by the want of obliteration of the fold of the nates. Besides, children are less liable to rheumatism than adults.

The *prognosis* of hip disease will vary according to the period at which treatment is commenced. In the first period of the disease, before the severe pain and the constitutional disturbance are developed, a cure may be effected, and the joint be restored to its original healthy condition. When the severe pain and constitutional disturbance are present before treatment is instituted, the further progress of the disease may be arrested, but in almost all cases there will remain a permanently rigid condition of the joint. Indeed, the same may be said of the period of suppuration,—an arrest of the malady will be followed by rigidity of the joint, shortening of the limb, and a loss of its function. In this last stage, recovery, if effected at all, will be very gradual, but the patient is more liable to loss of life from the constitutional sufferings and hectic irritation; the chances, however, are greatly better for children; adults almost invariably succumb.

The *post-mortem* appearances vary according to the period of the disease in which the examination is made. Although the disease never causes death until it has considerably advanced, yet, opportunities for post-mortem observations have occasionally been presented, where, patients suffering from the commencing symptoms of the affection, have died from some other cause. In its early period, inflammatory symptoms are observed; vascularity of the synovial membrane, with patches of opacity and softening, and sometimes a thickening from lymph deposits; the synovial fluid will be in somewhat larger amount; the articular cartilage may be softened, thickened, and of a grayish appearance, the round ligament will be red, swollen, and softened; vascularity, softness or brittleness of the osseous structure may also be present, with distension of its cells from deposition of semi-solid tuberculous matter. As the disease progresses, the morbid changes assume a more formidable character; there will be an augmented amount of lymph; partial destruction of the synovial membrane; ulceration of the cartilage; a carious condition of the bone; and evidences of an extension of the inflammatory action into other surrounding structures.

In the last period, besides the presence of pus, and the various canals through which it makes its exit, there may be an absence of the head and neck of the thigh-bone from absorption; or, necrosis of these portions of the bone; caries of the innominatum; perforation of the acetabulum, through which the pus passes into the pelvis and rectum; absorption of the ligaments; more or less complete destruction of the synovial membrane, the round ligament, and the articular cartilages; together with many other changes indicative of the destructive character of the disease. When the disease has

continued for a long time, fatty degeneration of the surrounding muscles has frequently been observed. The thigh-bone having lost its head and neck, will be found forced into some unnatural position. Evidences of tuberculous disease will also be found in other parts of the system.

The *treatment* of hip disease is divided into hygienical and therapeutical, and the latter is subdivided into local and constitutional.—In the early period of the disease, the local measures must be for the purpose of arresting inflammatory action, and consequently arresting the farther progress of the malady. The best means for attaining this result is, in the first place, to have the patient keep the limb and joint in a state of absolute rest and quiet; and this may be generally accomplished without the use of straps or splints. In the second place, the Compound Plaster of Belladonna, spread upon a piece of soft leather, about an inch or two in width, should be applied over the spinal column, extending from near the coccyx to the last lumbar vertebra; this should be kept on all the time, changing it occasionally, and only removing it for a short period when symptoms indicating absorption of the narcotics entering into its composition are manifested. In the third place, the Compound Tar Plaster should be applied over the hip, extending from in front of the trochanter around and posteriorly to the nates of the affected side, covering a portion of it, and especially its central and inferior portions. By means of this Plaster a more or less persistent discharge should be kept up for six or eight weeks, according to the strength of the patient, and the obstinacy of the malady. In some cases, hypodermic injections of a very weak solution of Chloride of Gold and Soda, associated with a weak solution of Muriate of Morphia, will be found very beneficial. These injections may be made at various points upon the upper and inner part of the thigh, the groin, inferior part of the nates, etc. Or, any other sedative may be employed instead of Morphia; in some cases, the Gold salt will answer a much better purpose, after the more active inflammatory symptoms have subsided; and the hypodermic injection of the Morphia Solution alone, will be better adapted to relieve the pain and inflammation, if too much disorganization of the parts has not taken place.

At the commencement, it may be necessary to give an active cathartic; but, as a general rule, it is better to avoid catharsis, and endeavor to keep a daily free condition of the bowels, either by mild laxatives, or by the use of laxative articles of diet. Internally, to aid in subduing the inflammatory symptoms, the following preparation should be given: Take of Tincture of Black Cohosh,

Tincture of Gelseminum, each, one fluidounce, Tincture of Aconite one fluidrachm and a half; mix. The medium dose of this preparation for an adult is twenty drops, every one, two, or three hours; it should be given, at first, sufficiently often to produce an appreciable influence upon the system, after which, merely often enough to keep up this influence. This preparation exerts both a sedative and antiscrofulous effect, on which account I prefer it to other sedative agents. Sleep may be promoted by the administration of opiates or other anodynes. As soon as febrile symptoms have been overcome, one of the alterative agents named under White Swelling must be administered, as, Compound Syrup of Yellow Dock, etc. And the state of rest in which the hip must be kept, as well as the exhibition of the alteratives, must be continued for several weeks after all symptoms of the disease have disappeared.—The diet in the early period should be moderate but nutritious, and the surface of the body, should be bathed daily with a warm, weak, alkaline solution.

If, however, the suppurative action has advanced so far that the above measures prove inefficient, we must then endeavor to promote its maturation and the discharge of the pus formed. For this purpose, warm fomentations may be applied over the whole hip, as well as over the Compound Tar Plaster, which must not be removed from its usual position upon and around the hip; Hops, Lobelia, and Stramonium Leaves, form a very excellent fomentation for the purpose just named. And as soon as a tendency to point at some place is observed, this point should be opened by means of caustic, that the matter may be discharged as soon as possible. During the whole of the suppurative and ulcerative period, the treatment will be similar to that named for white swelling: as, for instance, injecting the sinuses with Castile Soap-suds, followed by a Solution of Vegetable Caustic, or other solution, repeating this once or twice every day,—but, at the same time, keeping up the use of the Compound Tar Plaster, which may now be kept discharging intermittingly, if the patient can not bear it constantly, or, in case it occasions too much irritation. Tonics, alteratives, nourishing diet, and hygienic measures similar to those named under White Swelling, are also to be employed. Moderate exercise in the open air is admissible, provided the hip is properly secured by a splint, to keep it immovable; and the patient may walk on crutches, or be moved about in a small hand-wagon. He should be carried in the arms as little and as seldom as possible. Many months may pass, in the most favorable cases, before a permanent arrest of the malady will be effected, particularly after the suppurative stage.

BRONCHOCELE.

Bronchocele, Goitre, or Big Neck, is a chronic enlargement of the thyroid gland, which is much more frequently met with among women than men; it is very common among the inhabitants of certain mountainous districts, where it exists as an endemic, as, in the valleys of the Alps, the Apennines, the Pyrenees, the Jura, the Hartz, the Carpathians, the Cordilleras, the Himalayas, and in the mountainous districts of Tartary, as well as of the New England States, New York, Pennsylvania, Michigan, Virginia, etc. In many places it is associated with cretinism, or a degeneration of the human species, characterized by more or less marked idiocy, dwarfish size, misshapen head, and other physical malformations. Isolated cases in other sections of country are frequently met with, especially in moist places. And in countries where goitre is endemic, it is by no means uncommon to meet with the disease among certain domestic animals, as, dogs, hogs, horses, cows, etc. The disease has been considered scrofulous, but this is an error—the enlargement as frequently occurs among the non-scrofulous as the scrofulous.

The *causes* of bronchocele are not satisfactorily understood, though many reasons have been assigned for it, as, the use of snow water, or some particular saline or calcareous impregnation of the water in use as a common drink. It has also been attributed to the use of water in which there is an entire absence of iron, iodine, or bromine, this fluid being, at the same time, more or less stagnant and highly charged with lime. The disease is said to prevail in the older geological formations, as, in the silurian regions, and especially in the metamorphic, where the rocks consist of granular limestone, talcschist, talcose gneiss, micaceous schist, and other varieties, as is the case in the central Swiss Alps, and in places where the mica is so abundant that it is precipitated as a deposit from water when allowed to stand for a time. It also appears to exist endemically in magnesian formations, where the well water contains an abundance of magnesia. There is an apparent truth in these views, because, while bronchocele is seldom seen in systems of more recent origin, as, in the tertiary and cretaceous, as well as in coal meadows, which have more or less iodine, bromine, etc., well diffused throughout them, it is almost invariably met with in the older systems in which these non-metallic elements are wholly wanting.

Other causes have been named, and which may, undoubtedly, in many instances, tend to a development of the disease. Thus, it is frequently associated with derangement of the uterine functions, a

restoration of which to a healthy condition will very much facilitate the disappearance of the goitre. A prolonged residence in a moist location, conjoined with insufficient and innutritious food, sleeping in close, illy-ventilated rooms, or intermarriage of blood-relatives, may also occasion it. And rheumatism has been named as an occasional cause. The predisposition to the disease is often transmitted from parent to child.

There is no doubt but that goitre, especially in strumous, lymphatic, and bilious habits, is very frequently the result of a constant and excessive use of food of an amylaceous character, as, wheat flour, corn meal, beans, peas, etc., to the exclusion of a proper meat and albuminous diet. The amylaceous diet gives rise to a fermentation in the alimentary canal, and a consequent development of saccharine matter, carbonic acid, yeast plants, and others of low cryptogamic origin, etc., rendering the system highly glucogenic and fermentative, disposing it to goitre, intestinal irritation, flatulence, typhoid and enfeebling diseases, paralysis, cancer, etc.

The *symptoms* of goitre are readily made out. A small tumor is observed on one or both sides of the trachea, usually affecting both lobes, though unequally; or, it may be confined wholly to the isthmus of the gland; or to the isthmus and one of the lobes; presenting the appearance of either a uniform tumor extending equally on both sides, or occupying but one side, or two tumors with a fissure between them. There is no pain, no fluctuation, no unnatural appearance of the skin, and no derangement of the general health. As the swelling increases in size it may be hard, smooth, and uniform, or hard and rough or irregular; sometimes it extends back on each side so regularly as hardly to appear like a well-marked tumor. It generally increases very gradually, and not unfrequently it will remain stationary for a number of years, and then commence growing again, attaining an enormous size, and interfering with breathing. In most cases, the tumor is soft or spongy at first, and insensible to feeling, but as it enlarges it acquires a great degree of hardness, the skin becomes of a brownish or copper color, the veins varicose, and the voice assumes a coarser or husky tone. The face is also subject to flushings, with headache, giddiness, difficulty in respiration, and often shooting pains through the tumor. Severe or fatal cases are occasionally met with in this country; but the deformity is the principal source of annoyance and mortification to the patient. When the tumor continues to enlarge, becoming harder, with blood-vessels ramifying through it, the constitution finally becomes affected, and the patient ultimately dies.

There is a variety of bronchocele termed "substernal," or "suffocating," in which the tumor is a prolongation, as it were, of the thyroid gland, which extends behind the sternum and clavicle, and these bones preventing its development in front, it is thrust down against the trachea and its neighboring nerves, occasioning suffocating symptoms, or, symptoms resembling those of an asthmatic attack, from compression of the surrounding viscera. It requires a very careful examination, during the expiratory and inspiratory efforts, to detect it.

Goitre may be *discriminated* from *aneurism* by its slow growth, the absence of bellows sound, and its immediate reduction in size under the influence of the electro-magnetic battery. From a *varicose* condition of the internal jugular vein, by the tumor of the varix being seated lower down, as far as the superior margin of the sternum, being soft, elastic, compressible, bluish, and lessened in size by pressing upon the distal part of the vein. From an *encysted tumor*, by this being of small size, painless, soft, and somewhat semi-transparent; and, in case of doubt, the exploring needle may be used. From a *scrofulous tumor*, by the scrofulous constitution present, the existence of similar tumors in other parts, and by the liability of the scrofulous swelling to inflame and suppurate.

An *examination* of the internal appearance of goitre will discover a soft, gelatinous structure filled with a more or less viscid fluid, with numerous enlarged cells or cysts varying in size from that of a pea downward, and which, in the older, harder, and more irregular forms of the tumor, contain a dark, bloody-looking fluid, or melicerous, steatomatous, cartilaginous, or ossific deposits.

The *prognosis* of the disease is favorable when the tumor is soft, becoming considerably reduced in size during exposure to the action of an electro-magnetic battery. When the tumor is of very long standing, very hard, large, and containing more or less blood-vessels, treatment will rarely prove profitable. The earlier treatment is commenced, the greater will be the probability of cure.

The *treatment* consists of local and constitutional measures. A small quantity of the following preparation should be rubbed over the tumor once or twice every day, viz.: Take of Iodide of Potassium, Iodine, each, half an ounce, Hydrochlorate of Ammonia two drachms, Distilled Water half a pint; mix. Or, the above articles may be formed into an ointment by thoroughly incorporating all the ingredients, with the exception of the Water, with half a pound of prepared Lard. Or, the Compound Plaster of Belladonna may be worn constantly over the tumor. In conjunction with this, an electro-magnetic current should be passed through the tumor daily,

of sufficient power to reduce its size at each application, and each sitting should last for ten or fifteen minutes. Internally, the following agents will be found very useful: 1. Take of Iodide of Ammonium one ounce, Water one pint; mix, and after the Iodide is dissolved, give a fluidrachm for a dose, repeating it three times a day, and continuing its use for many weeks. It should be administered about an hour before each meal.

2. Take of Oleo-resin of Blue Flag one scruple, Baptisin five grains, Citrate of Iron and Strychnia eighty grains, Alcoholic Extract of Aletris eighty grains; mix thoroughly together, and divide into eighty pills. The dose is one pill, to be repeated three times a day, about an hour after breakfast, an hour after dinner, and at bed-time. I have frequently succeeded in effecting cures by the internal use of the Iodine Pill. Iodide of Potassium, Bromide of Potassium, Tartrate of Potassa and Iron, Citrate, or Bitartrate of Potassa, are agents that will frequently be found beneficial, when their use is persevered in for several months, in conjunction with the other local and constitutional measures.

A change of residence to a dry, pleasant spot, is always advisable; the liberal use of Ioduretted Salt with the food will be found very beneficial,—about twenty grains of Iodide of Potassium or Iodide of Sodium, to a thousand grains of common Table Salt. Rain-water, or spring water that has been boiled and then allowed to cool, will afford the best fluid for drink among those who reside in goitrous districts. In other respects the hygienic measures may be similar to those named under Scrofula. Eggs, oysters, fresh meats, milk, onions, cabbages, carrots, turnips, chicken, beef, and oyster soups, are important articles in the diet of a goitrous patient. Beans, peas, and all dry amylaceous food should be prohibited. Albuminous diet is highly proper.

The treatment for Suffocating Goitre is surgical. The tumor being transfixed by curved needles is to be raised, and then it is fixed in its new position by inducing an adhesive inflammation, which also aids in its partial resolution.

An ointment of the Biniodide of Mercury, five to ten scruples to the ounce of Lard, has been highly recommended by Dr. J. F. Mouat, Bengal, it having cured, as he states, from sixty thousand to seventy thousand cases of goitre. Some of the ointment is to be rubbed in well, over the tumor, for at least ten minutes, and then the goitre is exposed to the influence of the sun as long as the patient can bear it. In an hour or two, more of the ointment is rubbed in, and the case is left for several days, when the tumor generally disappears, or, at all events, is considerably diminished in

size, in which case the same operation can be repeated. It is very rarely the case that a third inunction has been required. The exposure to the sun is followed by a blister, but no pustules. I do not know whether any beneficial result has been obtained from this ointment in this country, but believe the treatment above laid down will prove fully as successful in effecting permanent cures, and with less danger of injury to the constitution. Besides, the question is, whether the beneficial results are wholly due to the iodine, and not to the mercury? Again, if we allow the Doctor fifty goitrous patients per week, it would require about twenty-three years to get through with the sixty thousand successfully-treated cases.

RICKETS, OR RACHITIS.

Rickets is a disease of the general system, which ultimately leads to a disease of the bones, characterized principally by a softening due to a deficiency of the calcareous or earthy deposits natural to them, and to a condition of the animal matter of the bones differing somewhat from that of healthy bone, there being frequently a partial or entire absence of gelatin. It is especially a disease of infancy, commonly appearing between the third and fourth month, though it is sometimes developed in the fœtus previous to birth, even when the mother manifests every appearance of health. Sometimes it may not be developed until at a more advanced period of childhood.

The *causes* of rickets are not understood. It appears to be more especially a disease of cold and damp places, and where there is an absence of the solar rays. The exciting causes are stated to be, raising infants by hand, feeding children who are suckling, insufficient, inappropriate, and unassimilable food, impure air, a cold and damp residence, want of exercise, uncleanness, and bad nursing. The disease is rarely associated with tuberculosis or scrofula, though such association has generally, heretofore, been held to exist.

The *symptoms* of the disease usually come on very slowly, and it is only after it has considerably advanced that we can recognize it. The child appears dispirited, is not disposed to move or be moved, suffers from pains in the bones during the night, and also whenever handled, crying out whenever it is touched or moved. Febrile attacks and abundant perspirations are common; paleness of the face, sallow and wrinkled appearance of the skin, deranged digestive functions, diarrhea, and calcareous deposits in the urine,

are also present. After a longer or shorter time, other symptoms are observed, the flesh becomes flabby; the body emaciated; the abdomen prominent; the face pale, swollen, or bloated; the head appears unusually large, and the sutures and fontanelles are preternaturally open. The pains in the bones become more acute, and the child cries out more vehemently, and especially during an examination of its limbs.

In connection with these symptoms, the bones, being unnaturally soft and unable to support the body, undergo various modifications or curvatures, especially those upon which there is much pressure or weight; the ribs lose their convexity; the sternum is thrown forward, forming a ridge; curvature of the dorsal and lumbar vertebræ is common, especially antero-posterior curvature; the femoral and tibial bones are generally curved forward and outward; the long bones of the arms may also be curved, and usually outwardly; the pelvis becomes distorted in various ways, and deformity of the female adult pelvis is sometimes owing to this disease in early life. Various other distortions appear, depending upon the well-marked character of the rachitis. The epiphyses at the several joints of the long bones enlarge, while the limbs between the joints appear very slender. There is always a prolonged delay in the appearance of the teeth, and they are apt to fall out early, not from their structure being altered by the disease, as they do not participate in the general osseous softening, but from the changes which the maxillary bones undergo. All these symptoms are not always present; and, in most cases, the softening of the bones is incomplete. The disease usually commences in the bones of the legs, to which it may be confined; or, it may gradually advance upward to the pelvis, vertebræ, etc. If the child is not eventually destroyed by great constitutional disturbance, and should live to adult age, the diseased bones may remain soft and yielding; more generally, they become very firm and solid, resembling ivory, but the deformity remains as at first.

The *diagnosis* of rickets can not be determined with any degree of certainty, until the limbs become painful and curve spontaneously or under pressure; when dentition is observed to be arrested; when the joints become enlarged; and when the fontanelles remain open. The spinal curvature may be determined from that due to other causes, by the distortions present in other parts, especially in the lower limbs.

According to Dr. Jenner, the leading features of rickets are, "mental capacity and powers small; muscular force deficient; mind and body inactive; figure short; closure of the fontanelles

retarded; face small, but broad; skin opaque, often set with downy hairs; the child is late in cutting teeth, in running alone, in talking, and its teeth drop early from their sockets." The leading pathological tendencies are, "softening of the bones; enlargement of the ends of the long bones; thickening of the flat bones, and deformities consequent on these conditions of the bones; so-called hypertrophy of the white matter of the brain; chronic hydrocephalus; pulmonary collapse; laryngismus stridulus; convulsions; albuminoid infiltrations of the liver, spleen, lymphatic glands, etc."

The *prognosis* of rickets is favorable at its commencement, for it is then more easily cured; but when there is extensive softening of the bones, and considerable deformity, it becomes more serious; for, notwithstanding the arrest of the disease, spontaneously or under treatment, the deformities remain unchanged, in many instances interfering with important functions, which may eventually terminate life. Rickets rarely proves fatal, except in those instances where the distortion becomes so great as to affect the functions of the heart, or lungs, or other vital organs; or when it is associated with mesenteric disease. Occasionally, the softening, and the associated constitutional symptoms, continue to increase, until every function of the system is affected, and death ultimately ensues. Infants at the breast are more exposed to peril than those who have reached three or four years.

Post-mortem examinations of the bodies of those who have died while still affected with rickets, have detected more or less important changes affecting the nutrition of one or several organs, as, of the brain, liver, spleen, lymphatic glands, etc. Sometimes, the ventricles, or cavities of the arachnoid, and of the spine are filled with a limpid fluid; the lungs may be compressed or displaced, when the disease has occasioned an alteration in the form of the thorax; the thymus gland may be enlarged; the muscles of the body and limbs may be pale, flabby, and wasted; and in many cases, both the liver and spleen will be found enlarged.

In the affected bones, the softening may be so great that they may readily be cut with a knife. The bones are enlarged at their extremities, from great development of the spongy tissue, and of the epiphyses. The spongy cells are filled with spongy matter, are enlarged, and contain a dark, bloody, gelatinous fluid, which may be removed by washing with water; at a more advanced period, this fluid becomes less black, more reddish and consistent, pulpy, adheres to the osseous walls, and becomes organized similar to the manner of false membranes, by means of capillary vessels of new formation. The calcareous granular deposit is wanting. The

periosteum of the affected bone is often more vascular than natural, and thickened. Thickening of the flat bones is due to this condition of the periosteum, together with the profusion of nucleated cells, and blood from the pulpy matter which occupies all the interstices of the bones. Free fluid fat may also be detected in the heads of the bones, especially in the reddish, semi-transparent pulp.

In the *treatment* of rickets, the first thing to be done is to secure a good bed, upon which the child can lie comfortably all the time, so as to relieve it from pain, and the diseased bones from pressure. One composed of equal parts of Dogwood and Sweet-fern leaves, will be found to have a very salutary influence; it should not be too hard, nor so soft as to yield much to the weight of the body. The body and limbs should frequently be bathed in a solution of Salt in Water, or in Brandy; and frictions with the open hand, or with warm soft flannel, should be frequently made. The bowels should be kept regular, without purging, and a good nourishing diet should be given, according to the age of the child; allowing the use of salt, cod liver oil, and butter. The child should be talked to in a cheerful way, frequently, so as to attract its attention, and excite and invigorate the brain; it should also be exposed as much as possible to the dry open air and sunshine, for which purpose it may be taken out on every pleasant day in a small wagon, adapted for this purpose.

As a constitutional remedy, a Syrup of Hypophosphite of Lime with the addition of a small portion of Hypophosphite of Iron, will be found an excellent remedy. A favorite agent of mine is the following: Take of the roots of Buckhorn Brake two ounces, Solomon's Seal Root one ounce, Comfrey Root half an ounce; bruise these roots, and add boiling water to them sufficient to form a paste or mucilage somewhat thicker than the white of egg. To this, when prepared, add the following mixture: Take of the Bark of the Root of False Bittersweet, Yellow Dock Root, Prickly-ash Berries, Caraway Seed, each, in fine powder, half an ounce; White Sugar one pound, good French Brandy one and a half pints. Let the whole stand for fourteen days, frequently shaking it, when it is ready. Of this compound, the dose is from a teaspoonful to a wineglass half full, according to the child's age, to be repeated every three or four hours. In addition to this, the whole length of the spinal column, the affected joints and limbs, and the abdomen, should be rubbed two or three times daily, with some stimulating preparation, as, the Compound Tincture of Camphor, or a lotion composed of two parts of Linseed Oil, and one part, each,

of Oil of Sassafras, Oil of Wintergreen, Oil of Origanum, and Camphor.

If the child is at the breast, the mother or nurse should be placed on tonic treatment, good animal diet, the use of the hypophosphites, and, when gastric acidity is present, prepared Chalk or Lime-water. As the disease is disappearing, and the child's health is improving, great care must be taken not to allow it to use its limbs too soon, nor at any period to exercise them too long at a time.

RHEUMATISM.

Chronic Rheumatism may be the result of an acute attack, or, it may manifest itself as a primary disease. When it occurs as a sequence of the acute form of the disease, the joints are usually affected, as well as the heart; when it exists as an idiopathic disease, the heart is rarely affected by it, and the joints frequently remain free from pain and swelling. The disease is much more frequently encountered among males than females, in the proportion of eight or ten to one. Generally, it is a tedious and obstinate disease to cure, from the fact that during the absence of actual suffering treatment is almost invariably neglected. The mere absence from pain during pleasant weather, or other favorable circumstances, is by no means a proof that the disease is eradicated, as patients who neglect treatment during the intervals of freedom from pain, generally learn to their cost, upon the approach and presence of damp and cold weather. If the disease be early and properly attended to, it is as readily curable as most maladies. It appears to be a disease of the fibrous, serous, and fibro-serous membranes more especially; and although any of these may be attacked by it, yet, as a general rule, certain localities are more obnoxious to it than others. Ordinarily, acute rheumatism affects the articular structures more especially; and chronic rheumatism, the muscles, their fasciæ, and tendons. The former is principally a disease of youth and early adult age, seldom occurring after forty years of age, unless it had existed previously.

As to the *causes* of rheumatism, there is no doubt but that exposures to damp or cold, or to sudden changes from a high to a low temperature, and vice-versa, very frequently occasion the disease, or, more properly, call it into activity—these being merely exciting causes, with many persons already predisposed to it; indeed, we observe that these exposures are often made, and to a very great extent, without a subsequent attack of rheumatism. Besides, the disease frequently occurs among persons who have

not been exposed to these exciting causes in the least degree. I have frequently seen it well developed among individuals, where the only apparent cause was the daily and continued use of alcoholic (spirituous and vinous) drinks in small doses, keeping the system constantly in an irritable condition; I have also known the use of acids, indigestible food, and functional derangement of the liver to be followed by severe attacks of this malady. A dry skin, a derangement of the renal functions, a night's dissipation, a constant exposure to a dry heat, etc., are frequently followed by an attack of rheumatism.

But, whatever may be the exciting causes of rheumatism, I have long considered it to be wholly a disease of the blood, and, probably, of those elements in this fluid upon which the integrity of muscular, or fibrous and serous tissues, depends. This abnormal condition of the blood may be a diminution of some of its alkaline constituents, or an excess of its acid. Fuller considers this abnormality of the blood to depend upon the presence of an acid, perhaps the lactic; and this may be the case—indeed, the perspiration of rheumatic patients has a more acid odor and reaction, than that of others, beside which, the urine is almost always more decidedly acid. The presence of lactic acid is supposed by some to occasion rheumatism, while gout may depend upon excess of uric acid in the circulation. It would be a very desirable matter to ascertain whether the injection of a small proportion of a solution of uric or lactic acid into the synovial fluid of the joints, would cause the active characteristic symptoms of gout or rheumatism.

Dr. Francis T. Bond objects to the lactic acid theory, upon the ground that it has not been shown to be in excess in the blood of rheumatic patients—that even supposing it to be present in excess, it would be difficult to trace the connection between this circumstance and the exudations in and about the different fibrous structures of the body—that an excess of other acids may be as much the cause of the phenomena as lactic acid—that as to the theory attributing the disease to suppressed perspiration, it is doubtful whether it is preceded by greater suppression than the prodromata of all inflammatory diseases bring with them—and that the tendency to sweating may be better explained by another theory. He considers that a hyperinotic condition of the blood exists from the first, and the excessive fibrin having a special affinity for the fibrous structures, is specially deposited in and about them. The weakness of a joint or its depressed nutrition, renders it more liable to be attacked. The increase in the perspiration and in the

acids, etc., of the urine, he attributes to the metamorphosis of the fibrin. The excess of fibrin in the system he considers due to imperfect primary assimilation—to a metamorphic process, normal in nature, but extreme in amount—and to defective elimination of the fibrin by the excretory processes provided for the purpose. The blood-poison, whatever it may be, effects more or less derangement and morbid changes in the fibrous and serous tissues of the system.

As damp weather approaches, nearly all persons experience certain unpleasant sensations of stiffness, fullness, relaxation or languor, and (when, at the same time, certain maladies exist), even pain—and with some, this sensitiveness to atmospheric changes exists to so great an extent that they are termed “living barometers.” Among the rheumatic, as damp weather approaches, more or less expansion of fibrous and serous tissues occurs, these expanded muscles or tissues press upon their accompanying nerves, producing more or less pain, according to the degree of pressure, as well as to the degree of sensitiveness of these nerves; and, as soon as clear, pleasant weather approaches, the muscle or tissue returns to its original condition, the pressure upon the nerves is removed, and the patient then becomes free from pain, and imagines himself well. When in addition to this peculiar susceptibility to the influence of atmospheric changes, the system is exposed to one or more of the exciting causes, this occasions more or less debility of the parts attacked, and renders them more sensitive when the rheumatic attack occurs, the symptoms being then more or less severe and persistent, according to the degree of debility and sensitiveness resulting from the exposure, and also according to the resisting power of the system.

The pain of rheumatism, although considered by many as the disease itself, is but a symptom of it—the disease is in the blood. If we press deeply between the dorsal part of the bases of the third and fourth metacarpal bones, so as to reach that branch of the median nerve lying in this location, at first, a rheumatic pain will be produced; continuing the pressure, a severe neuralgic pain will arise; and if the pressure be maintained sufficiently long, provided the person can endure it, the pain will gradually cease, a numbness will follow, and a subsequent paralysis, which will require several hours, or even days, to thoroughly remove. A somewhat similar effect is produced when persons accidentally hit the elbow on some prominent object, in which the ulnar nerve is suddenly pressed, pain is produced, and often a slight paralysis for

a few minutes. And these results are more readily and severely experienced by persons disposed to rheumatism.

The principal *symptom* of chronic rheumatism is a dull, aching, or gnawing pain, and which, even when articular swelling is present, is not attended by febrile or inflammatory disturbance. Every part of the system is liable to an attack, but the hips, loins, knees, ankles, shoulders, etc., are its more ordinary preferences. The pain may be confined to one particular part, or it may shift from one location to another; again, while some patients are hardly ever wholly free from pain, others suffer only on the approach of damp or cold weather, or from improper exposures. The pain in this disease is generally worse at night, while the person is in bed; while syphilitic or mercurial pains, which are seated in the long or flat bones, usually commence at three or four o'clock in the afternoon. In not a few cases, however, the warmth of the bed will be found to alleviate the pain. The joints are never swoln to the same degree as in the acute form of the disease, and the skin is pale, cold, stiff, and dry, with none of the redness of the inflammatory variety. If the affected part is allowed to rest for a short time, it will become stiff, and more or less pain will be produced upon attempting to move it; but, as the exercise continues, and the body becomes warmed, the stiffness and pain disappear.

In many instances, chronic rheumatism may be so mild in its character as to effect no appreciable influence upon the system, except it has existed for a very long time; while in others, its severity will produce some constitutional disturbance, as manifested by a quick and tense pulse, deranged appetite, variable appetite; irregularity of the bowels; coldness of the hands and feet; numbness of the limbs; and often, a partial impotency. If the disease be not cured, it will eventually occasion organic disease of the tendons, permanent stiffness of the joints, and an atrophy of the muscles adjacent to the affected part, with considerable deformity.—Persons laboring under rheumatic affections will generally have more or less soreness or pain produced by pressure upon the muscles on the sides of the neck, and frequently on pressure along the second, third, fourth, fifth, sixth and seventh cervical vertebræ, and upon the sacral nerves.

Chronic rheumatism has received several names, according to the parts attacked, among the principal of which, together with certain maladies strongly resembling, and heretofore confounded with it, are the following:

1. *Lumbago*, when the muscles in the lumbar region are affected.

In this form there is comparatively but little, if any suffering, until the patient attempts to move his body, when the pain becomes very severe; a sudden movement is especially painful. The patient can not stand erect, but assumes a bent position, inclining forward in walking. If the attack be very severe, he may not be able to move his body at all, without great pain, and will consequently be obliged to remain in a recumbent position for a number of days. In severe cases there will be some constitutional disturbance. It is a very obstinate malady, often resisting treatment for months. The lower limbs and joints are rarely affected.

It may be determined from *neuralgia*, by the absence of painful points on pressure along the affected nerve; from *lumbar abscess*, by the absence of any prominence, fluctuation and fever; from *disease of the kidneys*, by the character of the urine, and the pain excited by movements of the body; from *rheumatism affecting the vertebral articulations*, by an absence of swelling around the spinous processes, and no soreness upon pressure thereon. (See *Pains in the Loins*, page 294.)

2. *Muscular rheumatism*, the essential character of which is pain. The pain is not so severe as in *neuralgia*, is increased by pressure or movement, and is more persistent in its character. *Lumbago*, referred to above, belongs to this class. But it may attack any of the muscles of the body. When it affects the scalp, or the muscles of the head, as, the occipito-temporal, the masseters, temporals, or muscles of the eyes or cheeks, it is termed *epicranial rheumatism*, or *hemicrania*; the pain is greatly augmented when the muscle or muscles affected are suddenly moved, and is limited to these muscles. The malady is generally worse in the morning, especially in moderately cold and damp weather, at which periods it is more prevalent.

When it affects the muscles of the neck, it causes a "stiff" or "wryneck," "crick in the neck," termed *torticollis*, or *cervical rheumatism*. The pain is augmented by motion, the neck is sore, stiff, and is held inclined to one side.

When the the thoracic muscles are affected, it is termed *intercostal rheumatism*. The pain or stitch in the side or chest, resembles that of pleurisy, but is unattended with fever, and is aggravated by motion and by the act of breathing. Cough is not necessarily present; there is soreness on pressing externally; increase of pain upon elevating the arm above the head; and no febrile symptoms. It has also been termed *pleurodynia*.

A very obstinate form of muscular rheumatism is that which affects the muscles of the shoulder, and which, like the other

forms, has the pain aggravated on motion, and, in some instances, only when the arm is elevated. The muscles of the thigh or arm are likewise often attacked, and may become atrophied, giving rise to an emaciated limb, which is the result of disease of the painful muscles, allowing them to diminish in size and to ultimately have their nutrition impaired. Not unfrequently the rheumatism extends to the skin, occasioning a *rheumatic dermalgia*; the pain may be persistent, and mild, or it may be intermittent and severe, resembling the prick of a pin, or an electric shock, recurring frequently. Friction of the part with the fingers, or when the patient's dress passes over the affected part, always aggravates the pain, and sometimes occasions an acute burning sensation. The intermittent pain is worse at night.—Rheumatism may also affect the uterus and ovaries, at any period during pregnancy or non-pregnancy, more frequently the former; it gives rise to severe pains occurring in paroxysms; tenderness of the abdomen on pressure; and if the disease occurs near the parturient period, may lead to the erroneous idea that the pains are those of labor. If the uterine neck be examined per vaginam, the os uteri will be found closed, and exceedingly tender to the touch. Any motion aggravates the pain, and the patient lies upon her back, keeping as motionless as possible. After the pains pass away, they are succeeded in many instances by a profuse perspiration, or urination. If the pains come on at the time of labor, or near the parturient period, they become of an expulsive character, and may be a cause of difficult labor, by giving rise to irregular uterine contractions.

3. *Articular rheumatism*, or when the joints are affected, more commonly involves the ligaments and fibrous structures around the joints. There is no heat, redness, nor swelling, but a dull aching sensation, which becomes a more or less severe pain when the joints are suddenly moved; prolonged exercise of the joint lessens the pain. "When the bursæ and the synovial membrane lining the joint are affected, and effusion takes place into their cavities, the pain is usually less severe and less constantly aggravated by sudden motion; but it is more certainly increased by continued exercise, and is most felt when the limbs are in those positions in which the irritated membranes are put upon the stretch. Thus, when there is effusion into the capsular membrane of the knee, pain is sure to be induced by full flexion of the leg, and is greatly relieved by keeping the limb in a horizontal position, and straight, or very slightly flexed. And when the bursæ and the adjoining tendinous sheaths are the seat of effusion, any action which tends to bring the parts into play is certain to be accompanied by an increase of

suffering. The wrist is one of the common situations of these enlarged bursæ, and excessive pain is sometimes occasioned by long-continued use of the affected joint and of the tendons connected with it. In the chronic state, however, which I am now describing, although the swelling may be considerable, there is no remarkable febrile disturbance, no discoloration of the skin, and but little if any perceptible increase of local action." (*Fuller.*)

4. *Gonorrheal rheumatism* is the name given to a form of rheumatic affection of the joints, which manifests itself in connection with a urethral discharge; it is a very peculiar affection, the precise nature of which is not clearly established. Dr. F. C. Skey, in speaking of the disease, says: "There is no such thing as gonorrheal rheumatism, though there may be rheumatic gonorrhea." Fuller doubts its rheumatic origin. He observes—"My own conviction is, that the disease is due to the action of a specific poison, and has nothing in common with rheumatism as typified by rheumatic fever, except pain in the limbs and occasional swelling of the joints. Its origin is manifestly connected with a gleet discharge from the urethra, resulting, as I believe, from some peculiar form of vaginal poison distinct from that which occasions ordinary gonorrhea. Its course is unlike that of true rheumatism, . . . and it is unattended by any of the general symptoms which characterize true rheumatism." And he is, probably, correct in this view.

Although gonorrheal rheumatism presents the shifting character proper to all rheumatic affections, yet it manifests a greater disposition to localize itself, appearing to prefer the knee-joint, and may in some constitutions give rise to white swelling and ankylosis. The disease occurs among those persons who are laboring under a discharge from the urethra, or who, several years before, were attacked with rheumatism while suffering from gonorrhea. And persons who have once been attacked by this form of rheumatism are very liable to have a renewal of its symptoms whenever a urethral discharge is produced by any cause whatever, or shortly afterward, and sometimes even upon the slightest irritation of the urethra. It is more common to young persons of spare habits and energetic dispositions; and is, undoubtedly, a distinct affection having no connection with true rheumatism.

At the third or fourth day after the appearance of the urethral discharge, and sometimes not until two or three weeks have passed, the patient experiences chilly sensations, pains in one or several joints, especially the knees, shoulders, ankles, elbows, and wrists, and swelling from excessive synovial effusion, and inflammation of the ligaments and the adjoining bursæ and sheaths of tendons. As

the articular malady comes on, the urethral discharge may become diminished in quantity, or cease altogether. The pains are very severe and obstinately persistent, are generally aggravated by motion, but not upon pressure, may be more troublesome at night, and are often accompanied by wandering pains in the limbs. There may be some slight febrile disturbance at first, but this soon disappears; and the external surface of the affected part seldom presents any redness or inflammation. In the chronic form of this malady, more especially, there is little or no increase of the temperature of the external surface, the tongue is not necessarily furred, being often clean, the pulse is natural, the urine clear or natural, the appetite unimpaired, and, whether it be acute or chronic, it is never marked by inflammation of the heart. One symptom peculiar to this disease is an inflammatory condition of the eyes, or a conjunctivitis. The chronic form of the disease is, more particularly, very intractable to treatment.

As the disease progresses, the muscular and adipose tissues become wasted, which, in conjunction with the enlargement of the joints, gives a deformed appearance to the limbs. It may terminate by resolution, or it may continue a long time, eventually inducing serious organic changes in the affected joint, effusions into the areolar tissue, thickening of the periosteum, perichondrium, and other structures around the joints, especially around the ankles, occasioning permanent disability of the joints.

5. *Periosteal rheumatism* is commonly met with among the cachectic, the scrofulous, and those of impaired constitutions; it is the result of syphilitic or mercurio-syphilitic affections, or may arise from other causes. The parts of the periosteum, or fibrous covering of the bones, more especially liable to this malady, are those which, from having a thin tegumentary covering, are more exposed to changes of weather and of temperature, as, the cranium, the bridge of the nose, the sternum, the clavicle, the ulna, and the tibia. The disease is first noticed from the pain in the part, which is deep-seated, dull, and constant, and feeling to the patient as if seated in the bone; pressure over the part increases it. At first, there may be no redness nor swelling observed; but, sooner or later, a careful examination, passing the finger slowly along the bone, will detect a fullness or puffiness of the part, quite sensitive to firm pressure, which eventually disappears and is followed by a thickening of the periosteum, giving rise to distinct protuberances or nodes, which are frequently apparent to the sight alone. These nodes vary in size, seldom exceeding an inch and a half in length, have a rough feeling, are painful on pressure, and are a constant source of suffer-

ing. When located on any of the cranial bones, the pain may be mistaken for that of headache. In severe cases the system also suffers, the tongue becoming furred, the excretions deranged, etc. When the disease is located near or in a joint, as, the hip, or the shoulder, any movement of the joint will aggravate the pain.

The previous history of the case will enable the practitioner to determine its association with mercurio-syphilis, and generally other signs of the presence of this taint will be found to exist; the nocturnal pains will also be more severe, and the nodes will be larger, and usually more numerous. When the disease is of rheumatic origin, the pains and the periosteal malady are confined to one point, or to defined portions of one or more limbs; whereas syphilitic pains are shifting, affect a greater number of places, and are rarely confined to one part until nodes have formed. (See *Nodes*, *Osteocopic Pains*, etc., under Constitutional Syphilis.)

6. *Rheumatic gout* is a disease so closely allied to rheumatism that by some it has been considered a peculiar form of rheumatism; by others, a combination of rheumatism and gout; while a third class view it as a distinct disease, and which, in my opinion, is the true view. It may present itself in an acute form, and be with difficulty detected from acute rheumatism; or it may assume a chronic form. Persons who are debilitated or depressed from any cause, who are the offspring of tuberculous, gouty, or rheumatic parents, or in whom the function of nutrition is illy performed, are especially liable to it; either sex may be attacked, and at any period of life, but more commonly after the age of thirty, and especially among females. It is a very obstinate disease, passing from joint to joint, inflicting more or less injury upon them in its progress, often continuing for months, or even years, and producing changes in the structures of the joints which are irremediable.

The chronic form of rheumatic gout may follow the acute attack, or it may occur independently of this, presenting *symptoms* of languor, chilliness, and want of appetite, at the commencement, soon followed by a sense of fullness and stiffness of the joint attacked, and an aching or gnawing pain, which is aggravated by motion. All the joints are subject to attacks of the disease, but it usually prefers the knee, or the joints of the toes and fingers. The affected joints swell, from fullness and distention of the synovial membrane; the swelling is tight and elastic, and, as it were, protrudes through the spaces between the tendons and ligaments by which it is in other parts bound down and restrained,—and fluctuation, especially in the superficial joints, is distinctly perceptible. The periosteal covering of the ends of the bones, the ligamentous structures and other struct-

ures surrounding the joint gradually become more and more thickened, and more or less permanent stiffness and enlargement of the joint is produced. The soreness, stiffness, and pain generally extend from the joint along the fibrous structures to a greater or less extent, giving rise to severe pain in the limb. Eventually the cartilages become involved, they gradually disappear from absorption, and leave the articular surfaces of the bone bare and unprotected; while, at the same time, a morbid enlargement of the bone is going on, from expansion of its osseous tissue, and osseous deposit around the joint. The result of these morbid changes is distortion of the parts affected from the bones being partially dislocated, or being apparently drawn to one side or obliquely, usually toward the ulnar side of the hand, when the distortion is in the fingers.

When this disease affects the hip joint, there will at first be pain and stiffness of the joint; the pain becomes increased in severity; the affected limb becomes much shorter than the other, so that the patient appears lame; in some instances he merely rests the toes on the ground, or the foot is everted. Rotation of the limb is very painful and difficult, so that while walking there will be circumduction of the pelvis with the affected limb; the weight of the body on the diseased joint produces severe pain; the foot and the muscles of the limb become wasted from use; and the nates of the diseased side become flattened. When the hip is affected, the disease rarely extends to the other joints. This may be mistaken for some other malady of the hip, unless great care be taken in the examination, and inquiry be made to ascertain whether there have ever been previous pains or temporary swellings in any of the other articulations of the limbs. Males are more liable to the hip affection than females.

The general system is always more or less affected, the complexion may be florid but more commonly sallow or dingy; the skin is usually sluggish, with but little if any perspiration; the conjunctiva is yellow; the bowels more or less disposed to constipation, with a pale abnormal appearance of the feces; urine, pale, but generally turbid; pulse feeble; digestion may be good, but flatulence is very apt to be present, especially after meals; the temper is peevish, fretful, or irritable; the extremities cold; and a depressed state of mind, etc.

The *anatomical changes* in rheumatic gout, will depend upon the stage of the disease. At an early period the affected tissues lose more or less of their natural elasticity and brilliancy, and become thickened, opaque, and altered in color. Subsequently the synovial membranes become thickened, and, ultimately, gradual absorp-

tion of the cartilage takes place, this tissue apparently dividing into numerous fibers, forming depressions or grooves, which slowly enlarge, unite, and leave portions of the bone uncovered. The naked surfaces of the bones being thus exposed, are rendered smooth by pressure and friction against each other, and present a white, polished surface, having an appearance like ivory. The bony parts near the joints are also enlarged from osseous matter irregularly deposited about them. The thickened synovial membrane is prolonged at various points, forming soft, red, villous processes or fringes, which occupy the various depressions around the neck of the bone. Sometimes irregularly-shaped cartilaginous bodies, small, but of varying sizes will be observed attached to the ligaments or articular surfaces by pedicles formed of thickened synovial membrane; or, they may be loose in the cavity of the joint. If the disease be located in the hip joint, an alteration in the shape of the acetabulum and femur may be observed, from irregular osseous depositions, the acetabulum becoming wider and deeper than natural, while the femur becomes flattened and expanded, becoming shaped like a turnip, or lengthened into the form of a cone. The cartilages are absorbed, and the neck of the femur is shortened. Not unfrequently, the whole of the articular surfaces will be studded with a white pulverulent deposit; or, this may pervade their entire structure as well as the cells of the subjacent bone; or, it may be limited to a few parts only. This deposit is composed of lithate of soda, mixed occasionally with other lithates, chloride of sodium, and calcareous salts, and is probably due to the existence of true gout at some period during the patient's existence; it is not a necessary accompaniment of rheumatic gout.

In the *diagnosis* of chronic rheumatism great care is required to determine it from renal or vertebral affections, from gout, from simple or scrofulous inflammation of the joints, from neuralgia, and from syphilitic pains. To make the proper discrimination will often be a very difficult matter, and in some instances, it will be absolutely impossible, unless the practitioner is well posted in all the symptoms and peculiarities attending both the disease under consideration, and the various maladies with which it may be confounded. The diagnosis of the disease is, however, not always difficult, for its rheumatic character is frequently sufficiently well marked. Where the pains are wandering, first in one joint, then in another, and do not locate themselves in one place until after the presence of the shifting pains for some time, and not until a swelling of the part in which it fixes itself is apparent, there being

no febrile nor inflammatory symptoms present we may consider the affection of a rheumatic nature; if, however, there have been no previous attacks of rheumatism, no wandering pains in the joints, and the pain and swelling is located in some fixed place from the commencement, and especially if constitutional symptoms are present, the rheumatic character of the disease will then be doubtful. Pressure on the intervertebral spaces of the cervical vertebrae, or on the immediate neighboring muscles, most always gives rise to pain or soreness in rheumatic affections.

In most cases of chronic rheumatism, the *prognosis* is favorable, especially when the disease has been promptly and properly treated from the commencement, and when it is not the sequence of an acute attack. The malady rarely proves fatal, except when the larger joints are affected and abscesses are formed; but, when from improper treatment or long continuance, structural changes are effected in the tissues surrounding the joints, a cure is out of the question, and palliation is all that can be afforded. Besides, instances will occasionally be met with, in which, from some unknown cause, all our therapeutical and hygienical measures will be of no avail, even in cases, otherwise of an apparently mild character.

One great difficulty in effecting permanent cures of rheumatism, in any of its forms is, that patients instead of pursuing a curative course of treatment, direct their attention solely to a removal of one of its symptoms, *pain*, and when this has been effected, all further medication is dispensed with, until a second attack of pain occurs, when this symptom is again the only one attended to; and this course persisted in for several times, by not removing the diseased condition around the joints, permits the tissues of the parts to undergo such abnormal changes as to render a permanent cure entirely out of the question. As a rule, rheumatism is as curable a disease as any other, to effect it, however, not only must a treatment be adopted to relieve its accompanying pain, but the disease itself must be treated at an early period before structural changes have taken place, and especially must that condition of the fluids of the system upon which the disease depends be removed by appropriate medication.

The *pathological appearances* of parts which have suffered from chronic rheumatism will be found to vary, according to the nature, degree, and long continuance of the malady. Thus, there may be only an increase in the quantity of synovial fluid; or this fluid may become viscid, or even purulent; the synovial membrane and ligaments may be thickened, or roughened, with false membranes or

coagulable lymph deposited upon their surfaces. Softening, erosion, or entire destruction of the cartilages of the joints are sometimes present; with, perhaps, enlargement of the articulating extremities of the bones, and a relaxed or contracted condition of the muscles, tendons and ligaments. In some instances, thickening of the periosteum to a greater or less extent will also be observed. Indeed, whatever parts have suffered any considerable length of time from the disease, will be found to have their structures materially changed from that of a normal condition.

The *treatment* of chronic rheumatism is local and constitutional. The local measures are to remove pain, stiffness, and swelling, as well as to produce derivative influences; the constitutional are, to effect such changes in the system, not only of the essential rheumatic causes existing in the fluids, but also of other conditions or complications, as will prevent a recurrence of the attack, or modify its severity, and ultimately cure the disease.

Among the external measures, the Spirit Vapor Bath holds the first rank, particularly if the slightest degree of febrile excitement is present; free perspiration should be produced by it, and then after some one, two, or three hours, some stimulating application should be well rubbed in over the affected parts, as well as along the whole course of the spinal column. Ordinarily, if the pain and stiffness can not be removed by simply rubbing the parts, and by exercising them; or, if exercise should augment the pain; or, if the patient be too feeble, or can not from any cause, take a Spirit Vapor Bath, much benefit will be derived by exposing the diseased part to the vapor of hot water so as to produce and keep up a perspiration for thirty or forty minutes, after which the parts should be thoroughly dried, some stimulating application be well rubbed in, and the parts be covered with warm flannel.—When the Spirit Vapor Bath is employed, on no account must the patient be allowed to perspire freely for more than an hour at a time, on account of the debility occasioned by a prolonged diaphoresis. As the vapor bath is also an accompaniment of the constitutional measures, it should be repeated every week or two, according to circumstances, but the local stimulant need only be applied during the presence of pain or stiffness.—Hypodermic injections of a solution of Muriate of Morphia will frequently relieve the pain of rheumatism, in both the acute and chronic forms; they should be repeated every day or two.

There are many stimulating mixtures in vogue for this disease, but I ordinarily prefer the Compound Tincture of Camphor, or, the following, which slightly resembles it: Take of Tincture of

Capsicum, Tincture of Camphor, each, six fluidounces, Oil of Turpentine two fluidounces, Tincture of Aconite Root, Tincture of Stramonium, each, one fluidounce; mix. While the local stimulant is being applied with considerable friction, shampooing the diseased parts at the same time, when it can be borne, will be found exceedingly advantageous. Firing, over the affected joints, and over those parts along the spinal column which are tender on pressure, will also prove a valuable method of stimulation and counter-irritation, particularly in obstinate cases, and where the joints are deep seated, as, in lumbago, when the hip is affected, etc. And in very obstinate and painful cases, the Compound Tar Plaster over the suffering parts will be found decidedly beneficial; this plaster will prove very serviceable in cases where slight thickening or enlargement has taken place. Dry cupping or cupping with scarification along the lumbar vertebræ, and on the loins is frequently of great value in lumbago; so is the application of a Compound Belladonna Plaster; or the following may be applied: Take of Extract of Belladonna, or Stramonium, one drachm, Fluid Extract of Aconite four drachms, Compound Tincture of Iodine four drachms, Glycerin one ounce and a half; mix. And when the urine is high colored and scanty, with more or less constipation, cholagogue cathartics will frequently relieve the sufferings of the patient.

During the treatment, especially after the subsidence of pain, a gentle current of electro-magnetism should be passed through the parts daily, continuing the application for fifteen or twenty minutes each time. This agent, it must be remembered, is used only as an auxiliary measure to facilitate the action of the constitutional means; it will rarely, if ever, effect permanent cures by itself. It is of no value in the periosteal and synovial forms of the disease, but only in muscular rheumatism, and also in those instances where the pain assumes a neuralgic character. And, in such cases, hypodermic injections will often prove advantageous in relieving pain, as, of Sulphate of Morphia in solution, Sulphate of Atropia, etc.; they will also be often of service in the other forms of the disease.

In some instances much benefit will be derived by pouring tepid water upon the affected part, from a height of five or six feet, continuing this for five or ten minutes, then drying the part, and applying a stimulant with considerable friction. It may be repeated if desired.

Other local measures are frequently of service,—thus, the following will frequently remove the pain when other measures fail:

Take equal parts of Laudanum, Tincture of Camphor, Chloroform, and Fluid Extract of Aconite; mix. Or, take of Fluid Extract of Aconite, Chloroform, each, one fluidounce, Benzole two fluidounces; mix. Another very powerful agent is composed of Strychnia one drachm, Aconitina four grains, Oleic Acid two drachms; mix and dissolve the alkaloids, and then add to it Olive Oil or Simple Cerate one ounce. A small quantity of this may be rubbed over the painful part; but it must not be employed where the skin is cut, scratched, or in the least abraded, and none of it should be allowed to come in contact with the eye or mouth. The Ethereal Oil of Horse-chestnuts has also been valuable as a local application. The internal use of Chloride of Propylamin, in doses of six or eight grains, has also effected a removal of the pain, but in my own practice it has never appeared to have any influence toward effecting a permanent cure.

The constitutional treatment will vary somewhat, depending upon the patient's temperament, the disposition to scrofula, the presence of syphilitic taint, anemia, dyspepsia, etc.; and it should be faithfully and perseveringly pursued for many months, perhaps for a year or two, or, until the disease is cured. Of course, when structural changes about the affected parts have taken place, all that can be expected in most instances, is, palliation. Among the compounds which I have used with the greatest success, for neutralizing or removing the rheumatic poison, are the following:

1. Take of Poke Root, Blue Flag Root, Prickly-ash Bark, Black Cohosh Root, Bitter Root, each, in powder, one ounce; Whisky, two quarts; mix, and form a tincture; the dose of which is a table-spoonful in a glass of sweetened water,—repeating the dose three or four times a day.
2. Take of Black Cohosh Root, Prickly-ash Berries, Pipsissewa, and Sassafras Bark, each, one ounce; good French Brandy, two quarts; mix, and form a tincture. The dose is the same as the preceding.
3. Take of Compound Syrup of Silllingia, twelve fluidounces; Tincture of Black Cohosh, four fluidounces; Hydrochlorate of Ammonia, two ounces; mix. The dose is the same as the preceding. In periosteal rheumatism, one ounce of Iodide of Potassium, or Iodide of Ammonium, may be substituted for the Hydrochlorate of Ammonia.
4. Take of Black Cohosh Root, Bark of Sassafras Root, Prickly-ash Berries, Sulphur, each, in powder, one ounce; Guaiac, Poke Root or Berries, each, in powder, half an ounce; Colchicum Seed, two drachms; good Whisky or Gin, two and a half pints. Mix, form a tincture, filter, and add to it Precipitated Carbonate of Iron, half an ounce. The dose is the same as the preceding; shaking the preparation well, each time

before using it. 5. Take of Twin Leaf Root, Turkey Corn Root, Stillingia Root, Guaiac Resin, each, in powder, half an ounce; good Gin or Whisky, two pints; mix, and form a tincture. The dose is the same as the preceding. 6. Take of Alcoholic Extract of Black Cohosh four drachms, Xanthoxylin, (oleo-resin), Apocynin, each, one drachm; Whisky or good Gin, one pint. Mix, and dissolve the articles in the liquor. The dose is a tablespoonful, to be repeated three times a day, or sufficiently often to keep the head very slightly affected. The Ammoniated Tincture of Guaiacum, Compound Syrup of Poke, and Compound Pills of Poke, have also been found valuable remedies. Many other efficient agents have been used, but it would occupy too much space to name them all here; the above are such as I have preferred in my own practice. Perhaps, it would be proper to merely refer to such means as, acupuncture, bathing in hot springs, Pulvermacher's Belts and Chain Batteries, Sulphur, Sulphureted Baths, etc., which have proved efficacious in the hands of other practitioners. In my own practice, the Iodine and Sulphur Bath has proved very successful in syphilitic periosteal rheumatism, aided by the internal means recommended under the treatment of Secondary Syphilis.

But, in connection with these local and constitutional measures, the greatest attention should be paid to the general health. Any impairment of the digestive apparatus, any morbid condition of the liver, kidneys, or other organs, any nervous weakness, anemia, or torpidity of the cutaneous functions must be overcome by the appropriate treatment for such conditions; and the practitioner should always make it an important part of his examination to carefully mark each deviation from health, as may from time to time be developed, by the several methods of investigation at this day pursued by scientific medical men. Indeed, in the treatment of chronic rheumatism, much, very much, will depend upon the watchfulness and skill of the physician in early detecting these deviations and administering the proper remedies.

The bowels should be kept regular, daily; the kidneys should be maintained in as normal a condition as possible; and the skin should be bathed every day or two with a weak alkaline and stimulating bath, followed by considerable friction in drying. The body should always be comfortably clad, and every care be used to avoid cold and dampness; silk under-clothing may be worn in summer, and flannel during cold weather. Moderate exercise should be taken every day, and during pleasant weather, in the open air, but it should never be carried to fatigue. The diet should be moderate but nutritious, avoiding acids and fats, as well as vinous and malt

liquors. Sitting or standing near a fire, for any length of time, must be avoided.

Epicranial rheumatism may be removed by the employment of the local application above named, consisting of Chloroform, Fluid Extract of Aconite, Laudanum, etc.; or, by the application of a solution of Cyanuret of Potassium, one grain to eight grains to a fluid ounce of Distilled Water, and rubbed upon the parts, or applied by means of compresses moistened with it; internally, the agent for constitutional treatment, No. 3, will be advisable, in connection with cool affusion, and keeping the head covered in cold weather with a cap.

Cervical rheumatism may be relieved by the application of the chloroform preparation named in the preceding paragraph; or, frictions with some anodyne liniment, and then covering the part with warm flannel. If the uterus, ovaries, or other internal organs be attacked with rheumatism, the Compound Powder of Ipecacuanha and Opium, or, the Compound Tincture of Virginia Snakeroot, will be found to afford the most speedy relief, in conjunction with anodyne fomentations across the abdomen, or a Belladonna Plaster to the sacral region; or to such parts as will more decidedly influence the organ affected, when it is other than the uterus or ovaries. A mixture composed of Tincture of Black Cohosh, Tincture of Gelseminum, each, one ounce, Tincture of Aconite three drachms, will frequently be of benefit, in doses of twenty drops, repeated every two or three hours. Anodyne hypodermic injections will often afford prompt relief.

Gonorrheal rheumatism requires treatment to check the urethral discharge, for which purpose the means named under Gonorrhea or Gleet may be pursued; and internally, Iodide of Potassium, Iodide of Ammonium, or the Chloride of Gold and Soda, may be administered; in some instances, the following will be found efficacious: Take of Sulphate of Quinia twenty grains, dissolve in Elixir Vitrol one fluidrachm, and then add to the solution, Tincture of Black Cohosh twelve fluidrachms, Tincture of Aconite two fluidrachms. The dose is twenty drops every two or three hours in a tablespoonful of water. When the joints are painful and swollen, they may be painted once or twice a day with a preparation composed of Iodide of Ammonium one drachm, Iodine one scruple, Glycerin one or two ounces. Or, the Compound Plaster of Belladonna may be applied over them,—in all cases previously exposing the joint to hot vapor, as heretofore named. Hypodermic injections of dilute Solution of Chloride of Gold and Soda, will also prove beneficial in many instances. I have found the

continued use of genuine Harlem Oil, to afford much benefit in gonorrheal rheumatism. The Tincture of Larch (*Abies Larix*), in half drachm doses, repeated three times a day, is reported to have proved efficacious in this form of the disease. The conjunctivitis, that is usually present, may be treated by applications of a cool or tepid infusion of Hops, of flowers of St. John's Wort, or of Poppy Leaves, etc., renewed every few minutes, and continued for an hour at a time.

Periosteal rheumatism will require similar local applications to those named for the gonorrheal form; internally, Iodide of Potassium, or Iodide of Ammonium will be of service, and if the disease be connected with a syphilitic taint, measures must be adopted to remove this from the system; if the patient be scrofulous, or cachectic, the necessary remedies to overcome these conditions must be conjoined with those prescribed for the rheumatic affection.

Rheumatic gout, requires great attention to the condition of the digestive apparatus; when the tongue is coated brown or dark, emetics are indicated, to be followed by lemon juice in cachectic or scorbutic patients, in whom the gums are spongy, and the urine high colored and scanty. If gastric acidity be present, this must be removed by alkalies combined with tonics; as, for instance, a mixture of Bicarbonate of Soda, White Indian Hemp, and Aletris Farinosa, in powder—to which, in cases where the stomach is feeble, a small proportion of Capsicum may be added. Torpor of the liver may be overcome by the administration of a pill, repeated three times a day, consisting of three grains of dried Osgall, one grain of Leptandrin, and one grain of soft Extract of Rhubarb. And every means must be employed to prevent the stomach from becoming so deranged that it will not tolerate the medicines prescribed for the rheumatic disease.

The Compound Syrup of Sarsaparilla with Iodide of Potassium forms a very excellent remedy in this affection, but it requires to be used for a long time, and this syrup may occasionally be substituted by the Compound Syrup of Stillingia. Phosphate of Ammonia, in doses of eight or ten grains, repeated every six or eight hours, has been recommended by many physicians, but I have never employed it; it is stated to be especially useful in those cases where there is an excess of uric acid. Local applications, similar to those heretofore named must be frequently used, with thorough frictions over the affected parts. The frequent use of the flesh-brush will also be found very advantageous.

In all the forms of chronic rheumatism, great benefit will be

derived from the use of thin paper-like sheets of gutta pereha, or, vulcanized caoutchouc, being placed over the affected part after the application of the stimulating or sedative lotion employed; this is to be constantly worn. These sheets induce great local transpiration, and sometimes slight cutaneous irritation, and facilitate the action of the local application; they should be thin enough to be worn without inconvenience, about the thickness of paper. They are also useful to aid in allaying gouty pains. Free and regular exercise, active employment, an avoidance of all dissipated or intemperate habits, and the hygienical measures heretofore named, will be found of immense importance toward effecting a cure. Frequent applications of vapor to the joints affected, should be made. Where there is great debility of the nervous system, the Syrup of the Hypophosphites will be of service; if anemia be present, the Elixir of Cinchona and Iron may be taken with advantage.

In any of the forms of rheumatism herein named, there may exist either with or without swelling, a chronic thickening about the joints, or an effusion into the capsules, the bursæ, or the sheaths of the tendons, with more or less stiffness of the joints, especially the larger ones. The means to be employed to produce absorption of the effused fluid, and to prevent permanent contractions, are, applications of vapor to the joint, followed by electro-magnetism, considerable friction or shampooing, and painting the surface of the affected part with a preparation of Iodide of Ammonium and Iodine in Glycerin, referred to under Gonorrheal Rheumatism, over which a compress of soft lint moistened with the solution is to be placed, and a bandage should then be firmly applied. The bandage favors absorption. This may be repeated once or twice every day. The joint should likewise be gently moved backward and forward, and the limb be extended more and more every day, in order to prevent adhesions, which may ultimately give rise to permanent ankylosis; and, if required, some degree of force, gradually employed, may also be used to favor the extension of the affected limb. By a perseverance in this course for several months, many contracted limbs may be straightened. But if the ankylosis be permanent or bony, and the joint be distorted, no means will be of any avail. If, after the physician has explained to the patient the necessity for perseverance and long-continued treatment, the latter will not agree to continue under his care at least for some four or five months, it would be better not to commence treatment at all, unless, indeed, the practitioner has no regard for his reputation as a successful physician. For, usually, a much longer period will be required in cases

where a cure is at all possible; in some instances ten, or even fifteen months.

Rheumatism of the diaphragm is an affection of no uncommon occurrence, and may be mistaken for neuralgia, stomach disease, heart disease, pleurisy, etc., if not carefully investigated. The principal symptoms are pain in the region of the diaphragm; uneasiness or pain on a full inhalation; difficulty of breathing; asthmatic symptoms; rapid, irregular, and very forcible or bounding pulse, sometimes of one side only, and noticed more particularly in the neck, especially on the right side; cough; fainting; hiccough; palpitation of heart; and sense of constriction. The remedies are Iodine Pill, Irritating Plaster, Electro-magnetism, and some of the agents already advised in rheumatism, as, Compound Tincture of Black Cohosh, etc. The *hiccough* may be removed by inhaling Chloroform and repeating the inhalation as often as the symptom returns.

GOUT.

Gout is a painful disease, strongly resembling rheumatism in several of its symptoms, and is more usually met with among males, especially those of idle, indolent, sedentary habits, who live generously, using freely of animal food, rich sauces, wines, malt liquors, etc. It is not so common a disease in this country as in Europe. Three varieties of gout have been described, namely, the acute, chronic, and nervous. I shall briefly occupy myself here with the last two.

The *causes* of gout are not well understood; the disease appears to be due to an excess of uric acid in the blood, the result probably of some defect in the depurative function of the kidneys, or, perhaps, to a fault of assimilation, either primary, secondary, or both. Others doubt this view, from the fact that uric acid has been found in the blood during a rheumatic attack. Dr. Gairdner considers venous congestion to be the first condition essential to the formation of the gouty diathesis. The former view, viz., that there is an excess of uric acid in the blood, is the one ordinarily adopted at this day; this acid exists in the blood in the form of urate of soda, and can be separated from it, either in the form of the crystalline salt in acicular needles, or as rhombic crystals of uric acid. It has been noticed that just previous to an attack of gout the uric acid in the urine is diminished, but is accumulated in the blood, and during or subsequent to the attack, the acid is largely found in the urine. But whatever may be the proximate cause of the disease, it

is generally conceded that it may be excited into action by exposure to cold and damp, want of rest, violent mental emotions, improper diet, free use of acid wines and fermented liquors, constipation, digestive derangements, gastric acidity, sedentary and studious habits, or an indolent life conjoined with luxurious diet.

The *symptoms* of chronic or irregular gout, which is sometimes, but not always, a sequence of the acute, are, less severe pains than in the acute form, the pains being irregular and wandering, faint redness of the surface of the affected part, impaired power of motion, permanent distention and œdema of the part, derangement of the digestive organs, sluggish circulation, and general nervous irritability. Sensations of heat and coldness are apt to alternate in the part affected, particularly at night; there is also experienced numbness and a fullness and weight which is more or less annoying. The muscles and joints are weak; cramps in the legs are apt to occur when falling asleep; the surface of the part may be pale red, natural, or of a purplish tint; the parts are tender; motion is difficult and painful; and œdema is generally present with more or less varicose appearance of the veins. After walking, in almost all cases, a sense of heat and aching is felt in the ankles. In connection with these symptoms there will be constitutional ones, varying according to the temperament and habits of the patient, and other surrounding circumstances. Various dyspeptic symptoms may be present; hepatic derangement; transient pains or spasms in the muscles of the body; hemorrhoids; epistaxis; palpitations; disturbed sleep; irritable temper; depressed spirits; hypochondria; sallowness of skin; pale urine, of low specific gravity, in increased quantity; with diminution of uric acid, presence of albumen, and sometimes deposits of urates or colored rhombs of uric acid on cooling. Not unfrequently, the kidneys will be diseased, as determined by the presence of albumen, casts of the renal tubes, and disintegrated epithelium, in the urine, with diminution of uric acid. The affected joints are stiff and swollen, the limbs become painful and more or less deformed; deposits, principally of urate of soda, take place in the joints, and which are termed "chalky concretions," or "tophaceous deposits," forming small, hard swellings, called "nodosities."

Chronic gout may assume the retrocedent form; and it is often associated with some cutaneous affection, as, erythema, prurigo, fornication, eczema, lichen, psoriasis, etc. When gout attacks nervous persons, and those who have been somewhat careful in their habits, it is termed *nervous gout*. The pain is usually dull and lancinating, and may be confounded with neuralgia; it may be limited to a sin-

gle joint, or shift about, and may also be associated, like the preceding form, with dyspepsia, troublesome cough, difficult breathing, palpitation, etc.

In the *diagnosis* of gout, we must remember that rheumatism principally occurs among young persons, or those of middle age, while gout chiefly selects the elderly; rheumatism occupies the larger joints, and is very liable to shift about, while gout seizes the smaller joints, especially those of the feet and hands, and is not so liable to change about; rheumatism is seldom preceded by dyspeptic symptoms, gout almost invariably. The kidneys are more liable to be attacked by disease, in gout; the heart, in rheumatism. In gout, the chalky concretions are frequently found deposited in the joints; in rheumatism, this never occurs. An excess of uric acid in the blood is always present in gout, but not in rheumatism. This excess of acid may be determined by placing in a broad, flat watch glass, about three inches in diameter, a fluidrachm or two of the serum of the blood, fresh, or of the fluid procured from a freshly-blistered surface, and to each fluidrachm of fluid add six minims of ordinary strong acetic acid. When the fluids are well mixed, introduce into them a fine thread of unwashed linen, about an inch in length, and consisting of from one to three ultimate fibers. Now set the glass aside in a moderately warm place, not above 75° F., and allow the serum to become dry; but the drying must not take place too rapidly to interfere with crystallization, nor should the glass be disturbed until the drying is effected; it must also be protected from the dust. If uric acid be present in the fluid, its crystals will line the thread, and may be examined under the microscope, and under polarized light. If the serum be overdried, the operation will require to be repeated; and the part blistered must not be actually inflamed, or the result will be null. Oxalate of lime found in the perspiration, by a somewhat similar process, is also a characteristic of the gouty diathesis. In chronic gout, even when there are no tophaceous deposits in the joints, they may be observed on the helix of the ears, forming one or more little white spots, which, when recent, discharge a semi-fluid cream-like exudation, when punctured with a lancet; this, covered with a piece of thin glass, and examined under the microscope, will show, with a high power, a great number of needle-like crystals and a few blood disks. If a little of this exudation be heated with a small drop or two of diluted nitric acid, in a porcelain dish, and, when almost dry, be exposed to the vapor of ammonia, a beautiful purple color will be produced from the formation of purpurate of ammonia. If the deposit in the helix be

quite hard, as is apt to be the case when it has existed some time, it may be crushed, treated with water, and be experimented on in a similar manner. These deposits consist principally of urate of soda, vary in size from a pin's head to that of a split pea, are usually seated about the fold of the helix, numbering from one to ten or twelve, resemble small pearls, and when of long standing, possess a gritty hardness. (*A. B. Garrod.*)

Chronic gout is the disease of a degenerated or impaired constitution, its *prognosis* is unfavorable as far as relates to a cure; but although as a general rule it is absolutely incurable by any of the medical means at present known, it may be materially benefited by a proper attention to hygienic measures. As with the acute form, the chronic and nervous varieties may be translated to some one of the internal organs, as, the stomach, brain, or kidney, occasioning alarming symptoms, and even death. In forming a prognosis, the state of the constitution and of internal organs, the habits of the patient, the effects produced by treatment, and the surrounding circumstances should all be taken into account.

The principal *pathological appearances* are thickening and consolidation of the tissues of the affected part, and hard tophaceous concretions in the cellular membrane, the sheaths of tendons, the bursæ mucosæ, or, in the cavities of joints; if seated within the capsular ligaments, the cartilage will be absorbed, and one or more phalanges be distorted. In some instances, especially where the general health during life had been broken up, phosphates will also be found in the deposits, and, in plethoric or inflammatory conditions during life, the gouty concretions will contain more or less albuminous matter. And these deposits may often be observed in other parts of the body, as, in the fibrous envelops of the brain, nerves, fibrous coats of the arteries, fibrous tissues of the lungs and air-passages, fibro-serous membranes of the heart, in various muscular aponeuroses, in the fibrous coat of the testicle, etc.

In the *treatment* of chronic gout, the first thing to overcome is, the several constitutional symptoms, or derangements of organs, with which it may be associated, as, cachexia, nervous debility anemia, digestive, biliary, or renal derangements, etc.—employing the appropriate therapeutical measures therefor. At the same time a well-directed course of hygienic management must be rigidly pursued if the patient really desires benefit. And however useful medicines may be, hygienic measures are of much greater importance; a rigid, persevering attention to them has effected thorough cures.

*The principal hygienic means are exercise, temperance, and a spare regimen. A gradual approach toward a frugal and temperate style of living must be made, taking moderate and regular exercise daily, increasing it from time to time as the strength and condition of the patient will permit; late night hours and heavy suppers must be positively avoided. The patient must never sit down to a meal in a state of fatigue, or mental or physical exhaustion, because, in such case, his functions must necessarily be imperfectly performed,—and he must never overtax his strength. The body should be frequently bathed with a weak alkaline and stimulating wash, and, if the strength will permit, a Spirit Vapor Bath may be taken every six or eight weeks. The bowels must be kept regular, either by diet or medicine; any abnormal condition of the urine must be corrected by the proper remedies; and high living, indolence, sensual and intemperate habits must be positively prohibited. And, unless a patient laboring under chronic gout will agree to pursue these measures to the letter, a physician would not be justified in undertaking the treatment of his case.

Among the agents which may be employed to regulate the bowels, in very obstinate cases of constipation, the following will sometimes be found useful: Take of Acetic Extract of Colchicum. Extract of Nux Vomica, each, sixteen grains; Bicarbonate of Potassa twelve grains; Croton Oil three minims; Extract of Hyoscyamus twenty-four grains; Compound Extract of Colocynth one drachm; mix thoroughly, and divide into twenty-four pills, of which one or two may be taken at bed-time, whenever required. Lartigue's Pills have also been recommended. (*See page 312.*)

Several agents have been recommended internally, as possessing solvent power for urate of soda, but I do not think they exert any influence in removing the tephaceous deposits, although they may be beneficial in the early or acute form of the disease, in preventing these deposits in the joints. The principal ones which have been advised, are,—1. Silicate of Potash in doses of ten and fifteen grains dissolved in six or eight ounces of water, and repeated

*Dr Garrod gives the following as the indications necessary to be fulfilled in the treatment of chronic gout, viz.—1. Use less heroic means than those employed in the acute form; 2, purify the blood by augmenting the various secreting functions, more especially of the skin and kidneys; 3, restore the powers of the digestive organs, which are usually much impaired in chronic gout; 4, attend to the local mischief which the long-continued gouty inflammation induces in the articular structure; 5, regulate the diet, and pay proper attention to the hygiene of the patient.

twice a day. (*Ure.*) 2. Phosphate of Ammonia, ten or fifteen grains dissolved in a tablespoonful of water for a dose, and repeated three times a day. (*T. H. Buckler.*) 3. Benzoate of Ammonia, prepared by dissolving five grains, each, of benzoic acid and sesquicarbonate of ammonia, in two ounces of boiling water; this when cool is a dose, which may be repeated three times a day, with a little syrup. It is good in cases of irritable stomach, acts as a diuretic and diaphoretic, and diminishes the albumen in renal dropsy. 4. Iodide of Potassium is considered by T. S. Wells, superior to any other article as a chemical solvent, in doses of from four to eight grains three times a day. 5. M. Brian recommends Benzoate of Soda fifty-one grains, Hydrochlorate of Ammonia thirty-four grains, Senna thirty-four grains; mix, and keep in a close vessel. Fifteen grains is a dose, to be taken in water, and repeated three times a day, gradually increasing the dose to thirty grains. Acid food and drinks must be avoided, and exercise be enjoined. This also augments the urinary secretions, the cutaneous transpiration, and obviates costiveness. 6. Carbonate of Lithia in doses of one to four grains dissolved in water, and repeated three times a day. It is a most powerful chemical solvent of urate of soda. (*Garrod.*) If the affected joints could be kept constantly moistened with one of these solutions, probably, its absorption might aid in the removal of the gouty deposits. When the gouty deposit is not connected with the articulation, and has a pulpy feel, it has been advised to make a small subcutaneous puncture, slowly press out the pultaceous substance, and touch the exposed surface freely with Nitrate of Silver, which has the property of decomposing both urate of soda, and phosphate of lime. Fistulous ulcers may be injected with a solution of Nitrate of Silver.

When tonics are required in the treatment of chronic gout, the Citrate of Iron and Quinia, in doses of five grains a day; or, the Citrate of Iron and Quinia with Strychnia, in doses of from two to five grains, three times a day,—may be given either alone or in pill form with the Alcoholic Extract of Aletris. An infusion of the leaves of Ash (*Fraxinus Excelsior*) has been recommended in the treatment of chronic gout, in doses of four fluidounces, repeated three times a day. One ounce of the powdered leaves, made into an infusion, is the quantity required for a dose. Although highly extolled, it has not come into general use.

The following forms an excellent preparation for affording relief in an attack of gout: Take of Sulphate of Quinia two scruples, Extract of Colchicum one scruple, Digitalin one grain, Alcoholic Extract of Black Cohosh, a sufficient quantity to form a pill mass

mix, divide into twenty-four pills, of which one pill is a dose, to be repeated three times a day.—For agents which diminish or increase urea or uric acid in the urine, *see Gravel*.

CONSTITUTIONAL SYPHILIS.*

When the constitution is affected by syphilis, the result of a

* PRIMARY SYPHILIS. Although not comprised within the scope of this work, a few remarks relative to the treatment of Primary Syphilis, without entering into a description of its history, symptoms, etc., may not be amiss at this place.

Chancre. For more than thirty years past, when a chancre existed in the vesicular or pustular form, or unbroken, in which condition it is not acted upon by the atmospheric oxygen, I have been in the habit of rupturing the vesicle or pustule with a needle, and then at once applying a drop or two of strong Nitric or Hydrochloric Acid. I do not believe that absorption of the syphilitic virus occurs to any extent, until after the exposure of the open ulcer to the atmosphere.—Occasionally, this application of the acid will cause pain for a short time, but in most instances the pain will be slight. No other treatment will be required, unless to allay any fears the patient may entertain in regard to a perfect cure, for which purpose the chancre may be kept in contact with the Tincture of Chloride of Iron, on lint, as named hereafter. I have treated some hundreds of cases in the above manner, and have not yet heard of any return of the disease in a constitutional form.

When the chancre is open, as a general rule, the Tincture of Chloride of Iron will be found the most efficient application; I have used it with success, in by far the greater number of cases I have treated, since 1834. It should contain a sufficient quantity of Hydrochloric Acid, to enable it to be added to water without giving any deposit on standing for twenty-four hours, and which deposit may be prevented from occurring in the Tincture of the shops, by the addition of a sufficient amount of the Acid to it. The chancre having been first gently and carefully washed with Castile Soap-suds and as carefully dried with a piece of lint, is then to have the Tincture gently applied over its whole surface, by means of a feather or piece of lint, being careful not to rub or treat the ulcer roughly. This application is to be repeated two or three times a day, and during the intervals, a piece of lint moistened with the tincture must be kept in constant contact with the chancre. Sometimes this application gives rise to severe pain, when it should be diluted with as little water as possible; but, in most cases, after the second or third application, patients hardly notice it. It keeps the surface of the ulcer clean and soft, and prevents any absorption of syphilitic virus, by neutralizing or destroying it as fast as formed. Care must be taken not to allow a scab to form over the ulcer, as this will prevent the virus from being reached by the application. In a few days after its use, the chancre becomes changed into a simple ulcer, and it will often be difficult to detect it from the surrounding integuments, but which appearance must not mislead the practitioner and cause him to cease treatment too early. One thing must be especially attended to, as it is of great importance, which is, the parts and surrounding surfaces must be kept in a constant state of cleanliness. A filthy, unclean, careless patient is more exposed to constitutional symptoms than any other.

primary disease, it is termed "Constitutional Syphilis," and has been subdivided into two varieties, known as the *secondary* and *tertiary*. These varieties are due to absorption of the venereal virus into the general system, either from a chancre or bubo, and

Since I made the above method known, I find it has become adopted more or less, not only among the physicians of our own school, but also among those of the old school, etc.—Permanganate of Potassa employed as an escharotic at the commencement of a chancre, will also frequently destroy it.

In some cases of open chancre which appear obstinate and intractable, advantage will be derived by applying upon it a small portion of Fell's Chloride of Zinc Caustic (for Cancer), and then covering it with a piece of sticking-plaster; in two or three hours remove the plaster, and carefully wash out the caustic, and dress the part with some simple dressing, as, Nitrate of Bismuth, etc. In about three or four days, the slough can be removed, and the ulcer left may be treated with Nitrate of Bismuth, Tannin, or other simple dressing. This is painful but efficient. (*Prof. A. J. Howe.*) There are other applications which will sometimes be beneficial, as:—1. Take of Chloride of Zinc eight grains, Chloride of Gold and Soda four grains, Water one fluidounce; mix, and apply four or five times a day; if too severe, dilute with more water. 2. Take of Sulphate of Quinia twenty-four grains, Distilled Water three fluidounces, Sulphuric Acid, a sufficient quantity to dissolve the Quinia; mix, and apply on lint, first washing the chancres with Castile Soap-suds. Bear constantly in mind, that with whatever agents we treat a chancre, after it has become ulcerated, we must treat it kindly, and not irritate it and render it intractable by rough or harsh treatment. Constant irritation must positively be avoided.—If the glans penis be swollen, with more or less pain, a poultice of equal parts of Elm, Blue Flag, and Stramonium or Belladonna Leaves, must be kept constantly applied, renewing it every three or four hours. In one case, I derived prompt benefit from the constant application of ice water; the inflammatory symptoms disappeared rapidly.

Bromine has been recommended by Dr. J. J. Black, Philadelphia, as an application to chancre, acting as a caustic. It must be thoroughly applied to the chancre by means of a small glass rod, and an oiled rag be laid upon it for three or four hours; then remove the rag, and treat the part by the Potassio-tartrate of Iron mixture mentioned below under Phymosis, and which I prefer to the black-wash of Dr. Black. The eschar is eliminated in a little time, and exposes a healthy surface full of granulations. One or two applications of the Bromine are usually sufficient, and it is equally efficient in any form of chancre, especially the phagedenic.

Chancre is sometimes complicated with *phymosis* or *paraphymosis*. If it be phymosis, the following should be injected beneath the foreskin, so as to come in contact with the surface of the chancre: Take of Potassio-tartrate of Iron half an ounce, Syrup, Water, of each, three fluidounces, Wine of Opium one fluidounce; mix. This should be injected every hour or two; and if the patient desires to get thoroughly cured he *must* attend to himself. Glycerin may be substituted for the Syrup. In the intervals between the injections, the following mixture should be frequently applied upon the swollen prepuce, and, if necessary, even injected between the glans penis and prepuce: Take of Alcoholic Extract of Belladonna one drachm and a half, Oil of Lobelia forty-five minims, Glycerin one fluidounce; mix. The greatest cleanliness of the parts must be observed, in order to prevent gangrene.

may occur subsequently to a treatment of the primary affection, either with or without the use of mercurials. A thorough cure of the primary affection without mercurials, has never in my experience been followed by the constitutional disease, and I have treated

Cold water, or cooling applications, should also be kept constantly applied to the part.

If it be not positively known whether an ulcer be situated on the glans, in phymosis, we may determine it by giving a slight curvature to the end of a probe, cover it with a thin layer of lint, and then pass it carefully around between the glans penis and foreskin; pain will generally be produced when the ulcer is touched by this, and, on withdrawing the probe, some portion of the lint will be found stained by the chancreous matter; but if no ulceration exists, merely a discharge from the glans, no pain will be occasioned, and the lint will be stained with the simple discharge all over its surface.

Paraphymosis should be promptly reduced, by properly pulling the prepuce over the glans; thus, if it be considerable and painful, first give chloroform to produce anæsthesia; then apply Fell's Chloride of Zinc Caustic, in the manner named above, to the chancre, and afterward pull the foreskin over the glans, before the patient recovers from the anæsthesia; this is much better and safer than cutting the constricted part. Subsequently treat the phymosis by the anodyne and relaxing mixture named above; or by iced water, which will often be found to answer an admirable purpose. In the treatment of phymosis and paraphymosis, prompt measures should be adopted, as delay will render the case more difficult, and if the swelling remains for two or three weeks without being benefited, a very troublesome indurated enlargement of the prepuce, from hardening of the infiltrated matters, may result. The prepuce, it must be recollected, must be carefully and properly pulled over the glans, in paraphymosis, or the difficulty will be augmented. If it be impossible to reduce the paraphymosis, it may sometimes become necessary to divide the preputial ring, so as to relieve the constriction upon the penis, or to wholly overcome the paraphymosis.

If the chancre be seated *within the urethra*, it will generally be somewhere in that part of it passing through the glans; it should be treated by frequent applications of one of the above-named preparations somewhat diluted, which may be injected, or passed in upon some lint. A mixture of Sulphate of Iron five to ten grains, Water, Glycerin, each, half a fluidounce, has sometimes been found beneficial, when dropped into the urethra several times a day. Chancre in the urethra is frequently of difficult detection, and the discharge therefrom may render it liable to be mistaken for an obstinate gonorrhea; sometimes the ulcer may be seen by opening the lips of the meatus: when seated further back, the probe with lint, as named in phymosis, may aid in detecting it, as well as the slight degree of scalding in urination, the absence of chordee, the character of the discharge, and the interval which existed between the coitus and the appearance of the disease, which is generally from twelve to fourteen days, while that of gonorrhea is from three to six. Yet a person may, at the same time, have both a urethral chancre and a gonorrhea, the latter being developed some days earlier than the former.

Phagedenic chancre may be treated by the above-named solution of Potassio-tartrate of Iron; by a strong solution of Sulphate of Zinc; by Bromine; or by a Solution of Permanganate of Potassa one hundred and seventy grains, to Water

hundreds of cases, and also witnessed the treatment of many others by the means usually pursued by our class of medical men. These constitutional varieties appear to depend upon an imperfect

two fluidounces; apply every two hours; in the intervals keeping on lint moistened with a weaker solution. In phagedenic chancre, if the constitution be feeble, debilitated, broken-down, or adynamic, Quinia, Iron, Elixir of Iron and Cinchona, Procter's Compound Syrup of Hypophosphites, Porter, Ale, nourishing diet, mental and physical quiet, and all other means to nourish, strengthen, and invigorate must be pursued. Debilitating or lowering measures must absolutely be avoided.—*Serpiginous chancres* have been cured by applications of strong solutions of Iodide of Ammonium, or of Chlorate of Potassa.

Chancres in females require similar applications; they should all be treated under ocular inspection; the parts should be kept clean; the sores should be kept isolated by introducing pieces of lint moistened with one of the preparations used; and the female should be kept quiet in the recumbent position for several days.

Gangrene sometimes occurs, more especially among males; it must be treated with applications of Sulphate of Zinc; Solution of Permanganate of Potassa, etc.; and poultices of Marsh Mallow Root, to which Compound Solution of Iodine is added in small quantity. Attention must also be paid to the condition of the system, whether there be a typhoid state, or one of excitement, treating it according to indications, the same as is usually pursued in gangrene when attacking other parts, without the existence of a syphilitic virus. And when the sloughs have separated, healthy granulation may be promoted by stimulants, etc., locally applied, the same as in similar ulcers situated elsewhere.—*Hemorrhage* occurring during the treatment of chancre must be promptly checked; Tannin, or Perchloride of Iron may be applied, and, if these fail, torsion of the bleeding vessel with forceps, or ligature.—Troublesome and painful *erections* should be treated the same as chordee in gonorrhea.

Bubo should be dispersed as speedily as possible, on account of the many inconveniences attending its suppuration. If the tumor comes under notice before suppuration has commenced, it should be freely painted with Tincture of Iodine, or the Compound Tincture of Iodine, applying this six or seven times a day, and then covering with a pad or compress so worn as to make pressure upon the center of the bubo; or the Iodized Oil of Juniper may be used instead. If much inflammation be present, the constant application of iced water will be found sufficient. Fresh Poke Root, roasted in hot ashes until it is soft, then mashed and applied to the bubo, will disperse it, unless suppuration has advanced too far, in which case it will hasten its progress, but with considerable pain; on which account a cataplasm of Elm Bark, Lobelia, and Stramonium Leaves is then preferable.

In case of non-dispersion of the bubo, as soon as the suppurative stage has reached a proper degree of maturity or fluctuation, the bubo should be opened by Caustic Potassa, instead of the knife; the latter gives rise to everted edges which heal with difficulty, while the former disposes the abscess to heal readily. Some physicians prefer Vienna Caustic, cauterization with Nitric Acid, actual cautery, etc.; and others prefer the knife to the caustic. When the bubo is opened, it should be injected once or twice a day, with a mixture of three parts of Castile Soap-suds, and one part of Whisky, followed by an injection of Tincture of Chloride of Iron, diluted or not, Solution of Permanganate of Potassa, or the Solution of Potassio-tartrate of Iron named under chancre. Any sinuses which are present, if not too deep or extensive, should be laid open, and dressed

cure of the original disease, or from its treatment by mercurials, in certain constitutions.

The *Secondary* form of Syphilis is principally confined to external parts, and usually appears from two weeks to six months subsequent to the appearance of the primary symptoms. The *Tertiary* form is hardly ever manifested until after the sixth month, and sometimes, not until after several years, and attacks the deeper-seated tissues. Ricord states that, in cases where no mercury has been given, if secondary symptoms do not manifest themselves for six months subsequently to the appearance of the primary symp-

the same as the rest of the ulcer; and any fungous granulations may be removed with Sulphate of Copper, Nitric Acid, Tannic Acid, or by snipping them with scissors. In scrofulous patients, the Compound Solution of Iodine, or a Solution of Iodide of Ammonium may be employed to inject with; and these solutions may be made with water, or with equal parts of Glycerin and Water. These injections should be made two or three times every day, and the benefit will be much more prompt and rapid if the patient will keep quiet, on his back for the first four or five days of their employment.

If the bubo be *indolent*, a Solution of Vegetable Caustic, or other stimulating liquid may be injected; or Nitric Acid may be touched upon its surface by means of a soft piece of wood. If the bubo is *not open*, and is *very indolent*, showing but little disposition to disperse or suppurate, the application of a Compound Tar Plaster over it, keeping up a discharge for some time, will be very apt to remove it. *Phagedenic bubo* may be treated by applying lint to the whole surface of the ulcer, having previously moistened it with a strong Solution of Sulphate of Zinc, changing it two or three times a day; or with a Saturated Solution of Borax; or with the Potassio-tartrate of Iron Solution referred to heretofore.—If patients having bubo present enfeebled, adynamic constitutions, they will require the same tonic, nourishing, and invigorating measures as are advised under Phagedenic chancre.

As to internal remedies in these affections, whether they occur singly or together, I more generally employ the Syrup and Gold preparation recommended in the treatment of constitutional syphilis. I have also derived benefit from the Iodide of Ammonium in two to four grain doses, repeated three or four times a day, in solution. And sometimes from a mixture of Compound Syrup of Stillingia, Saturated Tincture of Poke Root, Saturated Tincture of Sheep Laurel, each, six fluidounces; the dose varies from a teaspoonful to half a tablespoonful three times a day, according to the effects of the Sheep Laurel on the system.—Iodide of Sodium two drachms, Cinnamon Water one fluidounce, in doses of twenty-five drops, repeated three times a day, has also proved successful.

The patient's diet should be generous, nutritious, and of easy digestion, avoiding acids, greasy food, stimulating or alcoholic drinks, and much exercise. Exposures to damp and cold must be carefully avoided, and the body should be very comfortably clad in cold and damp seasons. The use of salt is not prohibited, its prohibition in past times having originated from the fact of its decomposing the mercurial preparations which were so freely administered to remove the disease. Great care should be taken to prevent any of the virus from coming in contact with the lips, nose, or eyes.

toms, they never will be present. Sigmund, of Vienna, remarks that, secondary symptoms never appear if the chancre be thoroughly destroyed during the first four days.—The particular period at which the secondary or tertiary symptoms will develop themselves, will depend much upon the constitution and temperament of the person, his degree of resisting power to disease, mode of living, exposures, and other surrounding circumstances.

Although the *cause* of constitutional syphilis is an infection of the system from absorption of the virus of the primary disease, yet it often appears among individuals who never had the primary disease. Thus, it is generally conceded that the fœtus in utero, having secondary syphilis derived from its male parent, may communicate the disease to the mother, without her having ever suffered from the primary symptoms; and this communication of the secondary disease may occur as well in cases where from ultimate destruction of the fœtus abortion occurs, as in instances where it is born living. And it may be proper to state here, that abortion is by no means an uncommon occurrence, under the circumstances named; it usually takes place about the fourth or fifth month of utero-gestation, and a disposition to it, from the cause named, may frequently be cured by a proper treatment for the syphilitic taint.

It is not positively settled whether secondary syphilis is communicable by direct natural or artificial inoculation; yet from certain results from vaccination with matter taken from a person laboring under the constitutional disease, I am strongly inclined to believe that there may exist circumstances under which the disease is communicable by inoculation.

Indeed, there is more or less discordance among writers as to the contagiousness of the constitutional varieties. Ricord, who tried both natural and artificial inoculation without any results, believed that it was never contagious; others, in opposition to this view, believe it to be contagious,—that primary syphilis, by contamination, will produce primary syphilis, secondary, will develop secondary symptoms, and tertiary, tertiary. The matter requires still further investigation to satisfactorily determine it.

But, however this may be, it is well known, not only that the disease may be transmitted from parent to child, as stated above, and from the male to the female parent, but that, as frequently occurs, a child inheriting syphilis may, under certain circumstances, infect the nurse it suckles; and, on the contrary, as occasionally happens, a diseased nurse may communicate the malady to the child. There is also no doubt but that secondary syphilis may be

be communicated to a woman, without the intervention of pregnancy, by the semen of a diseased man being deposited in the vagina, and from thence absorbed, and that too without the presence of a chancre or any open sore on either of the parties. And, although it has been doubted whether the tertiary lesions can be transmitted to offspring under their peculiar type, yet that such transmission has occurred is, at present, a fixed fact.

The *symptoms* of constitutional syphilis vary very much, probably depending upon the difference of constitution, the medicines employed in the treatment of the primary form, the difference in constitution of the several parts attacked, etc. The disease may affect the brain and its meninges, the œsophagus, the bronchial tubes, the lungs, liver, kidneys, testes, and other organs.

Secondary syphilis is usually preceded, and sometimes accompanied by, more or less severe febrile symptoms, a dull earthy hue of the surface, loss of mental vigor, dryness of the hair, giddiness, headache, and uneasiness about the neck, followed by pains in the ends of the long bones, violent supra-orbital pain, lassitude, want of appetite and sleep, enlargement of the posterior cervical glands, weakness of the pulse, falling out of the hair and eyebrows, and anemia. The syphilitic poison diminishes the number of blood-globules, sometimes to such a degree as to give rise to anemia, with a bad complexion, dullness of the eyes, physical and mental depression, etc. These symptoms are eventually followed by some cutaneous affection in the form of dry eruptions, as large or small papulæ, scaly patches, and maculæ, which will be referred to under *Syphilides* in Diseases of the Integumentary System, *which see*. One peculiarity of these cutaneous eruptions, is, their yellowish or copper color, and their being almost always attended with a deficient sensibility of the surrounding skin, and, if they give rise to ulcers, the peculiar disagreeable odor emitted from them; occasionally, the eruptions will be met with, attended with itching and burning pain. In debilitated patients there may be red, inflammatory tubercles, gradually proceeding to suppuration, and giving rise to deep, irregular ulcers, which are more frequently met with at the alæ of the nose, or on the cheeks; this is an unfavorable form of the disease.

Reddish tubercles or broad rose-colored elevations, and occasionally excavations, often exuding a thin, acrid, and offensive fluid, termed mucous tubercles, mucous patches, or condylomata, frequently present themselves in the neighborhood of the genitals, upon the tongue, or in any place where two surfaces come in contact. These have an excoriated appearance, and may communi-

cate the secondary affection to healthy persons. These mucous patches are particularly apt to be present, and to prove extremely intractable to treatment, among uncleanly persons, and those who smoke or chew tobacco; among the latter, the patches are apt to be seated at the angles of the mouth, or upon the parts within. They are readily changed into ulcers, when exposed to friction. They have sometimes been observed upon the laryngeal mucous membrane, and upon the epiglottis. They frequently present a grayish-white appearance from the adventitious deposit of a grayish pellicle. Alopecia; onychia; ulcerations of the mouth and throat, of the meatus auditorius externus, of the lips and angles of the mouth, of the nose and palate, of the tonsils, of the gums, of the tongue, of the larynx, of the pharynx, of the eyelids, of the roots of the nails, with thickening and nodulation of the nails themselves, of the rectum and large intestines, and between the toes; excoriations and fissures of the surface of the tongue, or induration of its substance; excoriation of these several parts just named; iritis, scleratitis, dysentery, etc., may all occur as secondary symptoms; and it is rarely that they appear singly, two or more of them being usually associated together.

The various affected parts of the mouth may present a swollen and ulcerated condition, or, a rawness and redness, and covered with a white secretion; the ulcer of the throat or tonsil will present an excavation, with a foul, yellow surface, with raised, ragged, and swollen edges; or, there may be a sloughing ulcer, with irregular edges, ash-colored base, and dark, livid, and swollen surrounding mucous membrane, which may extend to various parts about the throat and nose, destroying them, and even endangering life from hemorrhage of the lingual artery. This ulcer is generally attended with febrile symptoms and considerable pain. These affections of the mouth and throat cause a soreness and difficulty in swallowing, and give rise to an offensive breath. If ulcers be at the angles of the mouth, they are apt to form scabs, and to bleed whenever the mouth is fully opened, as, in gaping.—When the nasal membrane is affected, it may terminate in caries and exfoliation of the nasal bones; or, from extension of the disease, the uvula may be destroyed.—When ulceration attacks the larynx, there will be more or less pain or soreness, huskiness, low whispering, or loss of voice, suffocative cough, and expectoration of a puriform matter streaked with blood. Deafness also frequently accompanies the ulcerated condition of the air passages.

These ulcers on the mucous membrane, wherever seated, proceed more or less rapidly, destroying the surrounding parts, giving

rise to more or less pain and fœtor, and often denude the periosteum of the bones of the parts affected, which afterward exfoliate. With these symptoms, the countenance assumes a more unhealthy aspect, the patient becomes more and more enfeebled and emaciated, is disturbed in his sleep, suffers from dull pains in various parts, and if not benefited, hectic fever will come on, followed by death. In ulceration of the larynx, death is frequently occasioned by suffocation. The improved treatment of the present day prevents us from seeing as many cases of this malady in its worst forms, as were commonly encountered some forty or fifty years ago.

In the hereditary syphilis of infants, we usually meet with pemphigus, and other cutaneous diseases; affections of the nasal and buccal mucous membranes; abscesses of the thymus gland; abnormal conditions of the liver, lungs, etc.

The *tertiary form* of syphilis* is known by the presence of tubercles, or gummy tumors, in the skin, cellular tissue, muscular and fibrous structures, and in other parts, passing into phagedenic ulceration. Among the abnormal changes effected, are, inflammation and enlargement of joints, inflammation of the periosteum, and disease of the testes, as, inflammation, enlargement, atrophy, etc.; osteitis; pains in the bones; exostoses; caries; inflammation and structural lesion of the eyes, eyelids, or lachrymal apparatus; serpiginous ulceration of the skin; deep ulcer of the fauces; phagedenic ulceration of the scalp, with or without disease of the pericranium and subjacent bones; phagedenic ulceration of the pharynx, which may extend into the larynx. cartilages, trachea, etc., or upward to the bones of the nose, face, and palate, or to the cervical vertebræ, causing caries; general syphilitic cachexia, with or without any prominent visceral disease, as, of the lungs, liver, etc., with paralysis, or dropsy, etc. And, as in the secondary form, although all these symptoms will not be present in any single case, several of them are apt to be associated. Secondary and tertiary symptoms may also co-exist; or the one

* Recently, a German physician has asserted that tertiary syphilis never occurs except in cases where the primary disease had been treated by mercurials; or, in other words, tertiary syphilis is a mercurio-syphilitic disease, partaking, however, more of the mercurial than of the venereal influence. He has found that persons working in mercurial mines, or otherwise constantly exposed to mercurial emanations, and who never had suffered from syphilis in any form, were very liable to diseases presenting, in every respect, the characters of what has long been termed tertiary syphilis—thus proving the truth of what has long been upheld by our class of practitioners, that constitutional syphilis was more of a mercurial than a venereal disease.

may pass into the other, and sometimes so insensibly as to render it difficult for a time to draw the line of demarcation between them, or determine which form has the predominance over the other. Other diseases, or tendencies to disease, frequently complicate the syphilitic affection.

The gummy tumors (*gummata*) are small, elastic tumors, conveying a sensation to the touch, as if they were filled with a gummy matter; they rarely appear before the fifth or sixth month from the period of infection, and frequently not until several years after. They may exist upon any of the external parts of the body, but are principally met with upon the head, neck, testes, and extremities, and vary in size from a large pea to a walnut. They commence as hard swellings, without pain or inflammation, and progress very slowly, ultimately becoming softer, tender under pressure, and as they reach the stage of suppuration, the skin over them becomes dark-red or livid, finally ulcerates, and discharges a thin unhealthy pus. The suppuration always begins at their center, and the ulcer produced by them is deep, the external orifice being partially covered by the thin and irregular margin of skin; the cicatrix left, is of a dirty white color, resembling that following a severe burn. Similar tumors are frequently observed in the muscles, viscera, tendons, liver, lungs, heart, brain, nerves, tongue, bones, periosteum, around the joints, etc. When located near the bones they are apt to produce caries or necrosis.

Syphilitic periostitis and osteitis present more or less tenderness and pain, especially in the more superficial bones, as, the clavicles, cranium, tibia, ulna, and nasal bones, which symptoms are augmented at night, and very much diminished or wholly absent during the day. The periostitis, after a longer or shorter time, is followed by painful swellings or nodes, which have a doughy feel, and an obscure sense of fluctuation; pressure upon them causes more or less tenderness, and the skin over them is pale and movable, at least until the swellings have progressed considerably. These nodes are due to an elevation of the periosteum from the bone by the infiltration of lymph and serum, or of pus; and the periosteum itself is more or less injected. Nodes present several characters according to their seat, and the character of the effused fluid; when they spontaneously ulcerate and discharge pus, the exposed bone is apt to become carious and exfoliate; and if the cranial bones are the ones affected, an extension of the disease to the dura-mater, or, a protrusion of the brain through the orifices formed in the skull, occasions death. The bones which are more apt to become carious, are those seated superficially, as, the nasal

bones, or frontis, etc., though no part of the skeleton is exempt. The symptoms of syphilitic cachexia, consist principally of pallor, sallowness, flabbiness of the tissues, auemia, mental and physical debility, emaciation, cutaneous diseases, loss of appetite, hectic fever, night sweats, want of sleep, diarrhea, aphonia, and finally death. This condition is now rarely observed, but it does occasionally present itself, in cases of syphilitic dyscrasia, as a result of the syphilis itself, of complication with a scrofulous or other weak constitution, of improper treatment, and of any cause which enfeebles the vitality of the system, as, sexual excesses, masturbation, dampness, cold, etc.

Syphilitic retraction of the muscles is occasionally met with in persons laboring under the tertiary form, the flexor muscles of the fore-arm, and especially the biceps, being more commonly affected: this symptom comes on without any warning, the first notice of it being a contraction or shortening of the muscles which the patient can not overcome, and there may be pain with it, which is worse at night. A proper therapeutical treatment for the syphilitic disease, will restore the muscles to their normal condition.

The *diagnosis* of constitutional syphilis is not always an easy matter, especially when it appears in the form of cutaneous eruptions, and when the patient will not acknowledge impure sexual contact, or the previous existence of the primary disease. In rare cases, the disease may exist, and the patient have contracted it without having been guilty of either of the above circumstances. Eruptions, either of an erythematous, scaly, papular, or pustular character, of a copper color, or reddish-brown with a tinge of yellow, soreness of the throat, osteocopic pains, loss of hair, enlargement of the glands around the occiput, the existence of nodes, an unhealthy aspect, dullness of the eyes, loss of flesh and strength, the indolent character of eruptions or ulcers, the deficient sensibility of the skin surrounding the eruptions and ulcers, and the presence of gummy tumors, are among the chief diagnostic symptoms; and the diagnosis is rendered more positive in case of a previous primary disease having existed. The cutaneous affections more generally observed, are, erythema, psoriasis, lepra, rupia, and ecthyma.

Dr. Brodrick refers to substernal tenderness as a symptom indicative of the existence of constitutional syphilis, which he has observed in numerous cases. If a patient supposed to be affected with the disease, does not, in reply to the question whether he has pain in his breast-bone, answer in the affirmative, the medical man should then press upon, or rather *knead* the sternum carefully and

gently along its whole course, with the fore and middle fingers, from the manubrium to the xyphoid cartilage; if tenderness be found, it will generally be located at the commencement of the lower third, and occasionally in the upper third. This tenderness, probably due to slight periosteal inflammation, may be considered a safe and unerring indication of constitutional syphilis, and is a sign that will furnish a clue to many anomalous symptoms. But a person may be constitutionally syphilitic, and this particular sign be absent.

In the diagnosis of the syphilitic dyscrasia, the practitioner should inquire into the previous history of the case, and not only ascertain the previous existence of a chancre, but the time of its appearance, its location, its character, and its duration; he should also remember that cases often happen where the patient may suppose he was only affected with gonorrhea, when, in reality, there may have existed a chancre in the urethra, or, in the vagina or cervix uteri of the female. The existence of a bubo at some previous time, or simultaneously with the chancre, should also be ascertained; indurated chancre is rarely attended by suppurating bubo. The penis and groin should also be carefully examined to detect any traces of indurated chancre or bubo.—Engorgement, not induration, of the lymphatic glands in the lateral and posterior parts of the neck, is considered by Ricord as probably the most constant, earliest, and characteristic symptom of constitutional syphilis. This engorgement may generally be detected about six or seven weeks after the primary symptoms, in most cases. Lymphatic glands in other regions may also be similarly affected.

Inherited syphilis is generally detected very readily in the infant, but in young persons and adults it is not always so easy to trace the disease. Mr. J. Hutchinson gives, as the most reliable symptom, the peculiar appearance presented by the permanent teeth,—especially the *upper central incisors* of the permanent teeth, *not* of the first set, or milk teeth. “In syphilitic patients these teeth are usually short, narrow from side to side at their edges, and very thin. After a while, a crescentic portion from their edge breaks away, leaving a broad, shallow, vertical notch which is permanent for some years, but, between the ages of twenty and thirty, usually becomes obliterated by the premature wearing down of the tooth. The two teeth often converge toward each other, and sometimes they stand widely apart. In certain instances, in which the notching is either wholly absent or but slightly marked, there is still a peculiar color, a dirty brownish hue, and a narrow squareness of form, which are easily recognized by the practised eye.”

He also describes other inferior but still important signs: "The skin is almost always thick, pasty, and opaque. It often shows little pits or scars, the relics of a former eruption; and at the angles of the mouth are radiating linear scars running out into the cheeks. The bridge of the nose is almost always broader than usual, and low; often it is remarkably sunk and expanded. The forehead is usually large and protuberant in the regions of the frontal eminences; often there is a well-marked broad depression a little above the eyebrows. The hair is usually dry and thin, and now and then (but only rarely) the nails are broken and splitting into layers. If the eyes have already suffered, a hazy state of the corneæ, and a peculiar leaden, lusterless condition of the irides, with or without synechiæ may be expected. If, however, the eyes have not yet been attacked by a syphilitic inflammation, they will present no deviation from the state of perfect health and brilliancy. The occurrence of well-characterized interstitial keratitis is now considered by several high authorities as pathognomonic of inherited taint. It is almost invariably coincident with the syphilitic type of teeth; and when the two conditions are found together in the same individual, I should certainly feel that the diagnosis was beyond doubt."

As a general rule, the *prognosis* of constitutional syphilis is favorable; much, however, depends upon the more or less advanced condition of the disease at the commencement of treatment, as well as upon the health and constitution of the patient, or, in other words, his degree of vitality. When the patient is young, and originally of good constitution, and not intemperate, the chances for recovery are in his favor, and especially if treatment be commenced at an early period. With an intemperate, dissipated person, or one given to excesses, or of irregular habits, or of a strumous tendency, the disease is always very difficult of cure, and in such cases the prognosis must be given with some degree of reserve. The prognosis is also less favorable when the constitution is much enfeebled, when the patient has passed middle life, and when the disease is complicated with other affections. Ulcerations of the pharynx are not always to be viewed favorably; and when they attack the larynx are very apt to prove serious. The more severe secondary symptoms, also, require a guarded prognosis.

In the tertiary form of constitutional syphilis the prognosis is not so generally favorable as in the secondary, although cures are frequently effected. When the mucous ulcerations assume a phagedenic character, or extend to the larynx, bones of the face, nasal bones, or to the eye, or if the cranium, or the cervical vertebræ become implicated, the case is very unfavorable. And the more

extensive the ravages of the disease the greater is the danger. In this variety of syphilis, the same as in the secondary, the patient's habits, health, degree of vitality, etc., should always be taken into consideration.

A *post-mortem* examination of a person who has died while laboring under the visible effects of constitutional syphilis, will reveal one or more of the several conditions described under "symptoms," together with whatever ravages, in the way of ulceration, caries, necrosis, etc., may have been effected. Internal organs will sometimes be found attacked by the disease, as, the brain, nerves, muscles, heart, bronchii, lungs, liver, spleen, and other viscera; exudations of lymph, gummy tumors, fibroid nodules, or deposits in the internal organs containing fibro-plastic elements, small nuclei, fatty granules, and some amorphous matter may be detected, with more or less disorganization of the surrounding tissues. A more minute investigation will almost invariably detect mercury in some of the tissues of the system.

The *treatment* which I have found the most successful in eradicating constitutional syphilis in either of its varieties is, the internal administration of alteratives, persisted in for *one, two, or three years*, according to the character and extent of the affection. And the statement made by various writers that Iodide of Potassium, and other agents, effect permanent cures in forty, fifty, or sixty days, must be received with great caution; my own experience, certainly, does not warrant any such statement, except in the less marked, milder, and more early symptoms of the disease. *A longer period is almost invariably required.*

The agents I prefer are the following: Take of Compound Syrup of Stillingia, Compound Syrup of Sarsaparilla, Tincture of Sheep Laurel, each, five fluidounces, Iodide of Potassium one ounce; mix. The dose is a tablespoonful, to be repeated three times a day, about an hour after breakfast and dinner, and at bed-time. In conjunction with this, I also administer the following: Take of Chloride of Gold and Soda ten grains, Hydrochlorate of Ammonia one ounce, Water one pint and a half; mix. The dose of this is from half a teaspoonful to a teaspoonful, repeated three times a day, about an hour before each meal. With these as internal measures, aided by local means hereafter stated, I have cured many cases of constitutional syphilis in this city and elsewhere, of several years standing, and which had previously resisted several thorough courses of mercurial treatment, in conjunction with Iodide of Potassium, under various physicians, without any benefit whatever.

Other practitioners have effected cures with other agents, as, the

Iodide of Ammonium; Arseniated Bromide of Potassium; Iodide of Arsenic; Iodide of Sodium, which is stated to have a less disagreeable taste than the Iodide of Potassium, to be less apt to occasion iodism, to be better borne than the Potash salt, and to have effected cures where this last named salt had failed, etc.

But whatever agent be used as a constitutional remedy, the bowels must be kept regular without active purgation; the surface of the body be bathed every few days; the renal functions be kept in as normal a condition as possible; and the condition of the stomach be closely watched, for if this be allowed to pass into a morbid or unhealthy state, it will materially interfere with the efficiency of the remedies administered; the diet should be generous, nutritious, and easy of digestion, avoiding all fats or greasy food, acids, alcoholic drinks, and active exercise. Exposures to cold or damp must be carefully avoided, and the body should be very comfortably clad in cold and damp seasons.

The local treatment of the secondary eruptions will be referred to under Diseases of the Integumentary System.

Alopecia will generally disappear under the constitutional treatment, but if any local application be required, a wash composed of Castor Oil two fluidounces, Tincture of Cantharides two fluidrachms, Tincture of Sheep Laurel two fluidrachms, Cologne one ounce and a half, may be well rubbed into the roots and scalp, daily. Tincture of Cinchona, or of *Stillingia* may be substituted for that of the Sheep Laurel.—*Syphilitic onychia*, and *whitlow* may be treated, by keeping the parts constantly moistened with a solution of Iodide of Potassium, or of Ammonium, in equal parts of Glycerin and Water. Hypodermic injections of a dilute solution of Chloride of Gold and Soda, in the neighborhood of the parts, will often be found effectual. If much pain is present, Opium, Belladonna, or Stramonium may be added to the application.

Mucous patches whether ulcerated or not, and *condylomata*, as well as the *deep ulcers in the fauces* and adjacent tissues, and syphilitic ulcerations of the mucous membranes generally, are best treated by Nitric Acid. A piece of soft wood, whittled down to the required size, is dipped into concentrated Nitric Acid, then wiped off with a piece of soft paper, and immediately applied upon the diseased part, holding it there for two or three seconds; this may be applied every day or two, according to circumstances. In some cases, the Tincture of Chloride of Iron, or, Tincture of Iodine may be similarly applied, with advantage. I have little or no confidence in the Nitrate of Silver, as a local application. If there is an *inflammatory condition of the throat* present, it will be found

advantageous to steam the throat, and apply anodyne fomentations externally. If the ulcers assume a *phagedenic character*, they may be touched with Tincture of Chloride of Iron, or with a solution of Potassio-tartrate of Iron one or two ounces to six fluidounces of Water; and, at the same time, half a tablespoonful of this latter solution, may be taken for a dose, internally, and be repeated three times a day, in conjunction with the constitutional treatment. A dilute solution of Permanganate of Potash, has also proved valuable and efficacious as a local application. Chlorate of Potassa, used both locally and internally, will frequently be found to exert a very beneficial influence in syphilitic *sore throat* and *sore mouth*. Gargles are likewise frequently of service, as, solution of Tannic Acid, equal parts of infusions of Black Cohosh and Wild Indigo, solution of Chlorate of Potassa, infusion of Geranium and Black Cohosh, equal parts, etc. *Deep fissures in the tongue* may be treated by Tannic Acid in solution, by Liniment of Verdigris, by Nitric Acid, or by solution of Chloride of Gold and Soda. If there are any *swollen glands about the throat*, a solution of Iodide of Ammonium, one scruple to an ounce of Water, or, the Compound Ointment of Iodine, should be well rubbed in the part, twice a day.

Gummy tumors when hard, may be treated by painting them with Tincture of Iodine, or, by keeping the parts constantly moistened with a solution of Iodide of Potassium, or Iodide of Ammonium, in equal parts of Glycerin and Water. Hypodermic injections of a dilute solution of Chloride of Gold and Soda, may also be made into or about them. When they are soft, fluctuating, they may be opened, and the ulcer be frequently injected with one of the above solutions; or, if they have a phagedenic tendency, the above-named solution of Potassio-tartrate of Iron may be injected; or they may be treated in the same manner as other phagedenic ulcers. These tumors frequently yield to repeated blistering.—*Syphilitic affections of the nasal passages*, if they can be reached, should be touched with Nitric Acid; otherwise, a solution of Chlorate of Potassa may be injected, composed of Chlorate of Potassa two drachms, Concentrated Hydrochloric Acid forty minims, Water one pint; mix. A dilute solution of Perchloride of Iron; of Tincture of Chloride of Iron; of Permanganate of Potassa; and a solution of Arseniate of Soda, one, two, or three grains to a fluidounce of Water, have likewise proved of efficacy; but I do not recommend the last-named agent.—*Ulceration of the larynx* requires to be carefully treated by touching with Nitric Acid; this may be effected by means of the laryngoscope, and a curved porteaustic, carrying a small piece of soft wood saturated with the

concentrated acid; the application should be repeated every day or two, and the throat should be gargled in the interval, two or three times a day, with the solution of Chlorate of Potassa; or with one of the heretofore-named gargles. At the same time, the Compound Iodine Ointment may be rubbed upon the parts, immediately external to the ulceration. Inhalations of warm medicated vapors, containing anodyne and balsamic substances, may often be employed with advantage.

Syphilitic affections of the *eyes* and *ear*, are treated upon under Diseases of the Eyes, and also, of the Ears.—*Osteocopic pains* may sometimes be benefited by the use of a pill composed of one or two grains of Inspissated Juice of Poke, (or the Alcoholic Extract), and one-fourth of a grain of Alcoholic Extract of Stramonium; two or three of these pills may be given daily. I have frequently found great relief, in cases of severe osteocopic pains, to follow the use of a mixture, thoroughly rubbed over the affected parts three or four times a day, composed of Iodide of Ammonium, Iodide of Cadmium, each, half an ounce, Fluid Extract of Aconite, Alcohol, each, four fluidounces,—mix; and in the evening, when the pains come on, also apply a rag moistened with the following preparation over the affected part, then cover it with a dry compress, and repeat the application as often as desired: Take of Chloroform, Benzine, Alcohol, each, two fluidounces,—mix.—Hypodermic injections with Sulphate of Morphia, every day or two, in the neighborhood of the painful part, has also been used by Prof. Scudder with excellent results. Painting over the part with Tincture of Iodine, or, the application of the Compound Plaster of Belladonna, and, in some instances, the use of blisters, will frequently give relief. With the exception of the blisters, a similar local treatment may be pursued for *nodes*.

It is not advisable to open nodes, unless they are large and painful, or give distinct fluctuation, in which case, a free incision should be made, bringing the knife in contact with the bone; and applying some anodyne and stimulating preparation to the ulcer thus formed, if it becomes indolent, showing but little tendency to heal. *Nodes* on the *lower part of the tibia*, and *syphilitic affection of the ankle joint*, may frequently be benefited by friction, twice a day, in the warm Nitro-muriatic Acid Bath, without the use of iodine paint or blistering; the bath may be made by adding nine fluidrachms of Hydrochloric Acid, and six fluidrachms of Nitric Acid, to each gallon of Water employed.—In both the secondary and tertiary forms of syphilis, I advise Vapor, or rather Fume Baths, two or three times a week, of a combination of Sul-

phur and Iodine; when these are taken in conjunction with the constitutional treatment recommended, it is astonishing to witness how rapidly the osteocopic pains, nodes, etc., disappear. These fume baths, and the internal treatment, should be persevered in for several months, and ought never to be neglected in the treatment. (See *Periosteal Rheumatism*, page 430.)

Caries and *necrosis* require the ordinary treatment for these conditions.—*Warts* may be cured by a solution of Chromic Acid, one hundred grains, in Water one fluidounce; this should be applied by means of a glass rod,—it produces a slight burning pain, and one application usually removes the wart in the course of six or seven days. Other remedies have been recommended, as, Savin Leaves, Muriate of Ammonia, Nitric Acid, Manganic Acid, etc.

If there is any suspicion of a syphilitic taint, during pregnancy, or where frequent abortions occur from this taint, or where the offspring are born inheriting it, one or both parents should be subjected to the above treatment. Infantile syphilis may be treated by the constitutional remedies above named, being careful to so regulate the doses as not to disturb the stomach or digestive functions; the disease is always a serious one, and requires much care and judgment in its management. Minute doses of Arseniate of Soda have been highly recommended in this disease, by those who have tried it, but I feel confident that the disease can be cured without it.

PURPURA HEMORRHAGICA.

Purpura Hemorrhagica, or Land Scurvy, is a disease consisting of an exudation of blood, forming reddish, purplish, or livid spots or patches in the cutaneous surface, of various sizes, and irregularly scattered over various parts of the body. There are three forms of this affection, viz.: 1. *Purpura simplex*, or purpura without hemorrhage, in which the petechial spots are minute, varying in size from a point to that of a small pea, distinct, purple, not itching, not disappearing on pressure, and distributed on various parts of the external surface, being preceded and accompanied by languor, muscular debility, pale and sallow complexion, yellow coat on the tongue, impaired appetite, nausea, headache, constipation, etc., and which under ordinary circumstances may be readily cured by pure air, nutritious diet, regular exercise, moderate use of wine, quinia, and the mineral acids. If the disease be neglected, it may pass into the second variety. 2. *Purpura hemorrhagica*, the

one under consideration, and which is the most dangerous form. 3. *Purpura senilis*, or scurvy of old age, which is a rare disease, and is more frequently observed on the inferior extremities among elderly persons, especially females.

The *symptoms* of purpura hemorrhagica may be manifested suddenly, or the disease may be preceded, for some days or weeks, by great debility, and by the constitutional symptoms referred to above, but in a more marked degree, so that the patient is incapable of any exertion. The petechial spots are frequently quite large, more numerous, more irregular, and of darker color, than in the simple form, often resembling the marks left by a severe bruise, *ecchymoses*, or the stripes resulting from blows with a whip, *vibices*. They more generally commence on the extremities, and extend to the body, but are rarely observed on the hands or face. The spots are at first bright red, soon become dark or purple, and, before disappearing, become of brown or yellowish tint. The cuticle is not elevated, except in some rare cases, in which the elevation resembles a blister or vesicle containing dark blood. The least pressure on any part of the surface of the body will produce an exudation of blood, and purplish spots or patches like those already present.—Exudations of blood, from mucous surfaces especially, take place, and more or less profuse hemorrhages, or oozing of blood from either one or more of the following organs, as, the mouth, gums, nostrils, lips, tongue, fauces, ear, conjunctiva, urethra, vagina, etc., are usually present; and, sometimes, profuse, and even dangerous hemorrhages from the internal surfaces are met with, as, from the stomach, bowels, kidneys, lungs, bladder, uterus, etc.—The disease is often attended with febrile symptoms, but almost always with extreme debility, depression of spirits, deep-seated pains in various parts, constipation, emaciation, feeble or rapid pulse, bloating of the extremities, impaired digestive functions, etc. The urine is generally of a dark color, of an alkaline reaction, containing a large amount of earthy phosphates, emitting an ammoniacal odor, and soon becoming offensive.

The *causes* of purpura hemorrhagica are not well understood. It appears to be due to any cause that will impair the vital tone of the system, of the capillaries, and of the blood. Living in cold, damp, or crowded places, impure air, depressing moral emotions, use of animal food, and especially without salt, diseased animal meat, dissipation, intemperance, want of proper nourishment, etc., have been named among the causes; though I have met with two cases in which the patients were previously apparently healthy, and were not, as far as I could ascertain, exposed to

any of the causes just named,—in one of them, a young girl about fifteen years of age, it accompanied an attack of amenorrhea.—The disease is sometimes met with following other diseases, as, scarlatina, measles, small-pox, intermittent and remittent fevers, diseases of the liver and spleen, as, atrophy or hypertrophy, etc.

This malady may occur at any period of life, being more common among women, and in males just arriving at puberty. Its duration is very uncertain and irregular; it may disappear in a few days, or may remain for months or even years, eventually causing death by a sudden and profuse hemorrhage from some important organ, or, by a less profuse but constant hemorrhage from two or more organs simultaneously.

The *diagnosis* may be readily made out by the symptoms already described. In *true scurvy* the ecchymoses are larger, more marked on the extremities, the gums are more prominently soft and spongy, and there is a greater degree of mental and physical debility toward the latter period of the disease, than is met with in purpura. (*See diagnosis of Scorbutus.*)

The *prognosis* is more favorable in the variety attended with petechiæ, than that with ecchymoses; although both varieties are of a serious character. The unfavorable symptoms are, small, rapid, and weak pulse, frequent recurrence of hemorrhage, thin and watery, or non-coagulable blood, presence of anemia, or cachexia, vomiting of black, grumous matters, diarrhea with grumous or bloody evacuations, faintness after the evacuations, hemorrhages from the tongue, lungs, or urinary organs, and, when they do occur, lethargy, coma, or apoplexy. Death is usually due to the amount of hemorrhage, internal or external, occurring suddenly, or by exhaustion of the vital forces. When the disease is promptly and beneficially influenced by treatment, the symptoms gradually disappearing, the case is a favorable one; also when the attack is mild, and unaccompanied with the more severe symptoms.

The *pathological appearances* vary considerably; petechiæ or ecchymoses may be observed on the mucous membranes of various internal organs, as, the lungs, pleura, pericardium, abdomen, liver, spleen, kidneys, bladder, brain, etc. There may also be more or less effusion of blood into the serous cavities, or into the tissue of the parenchymatous organs. The tissues are more or less soft and friable, especially those of the liver and spleen. The blood may resemble that of health, or it may present a light red, translucent, tremulous, jelly-like appearance, not separating into serum and coagulum, and is generally very deficient in fibrin and coloring matter.

The *treatment* of purpura hemorrhagica consists, principally, in the administration of tonics and mineral acids. Manganese, combined with Iron, will frequently be found efficient when Iron alone fails—thus, Pills of Iron and Manganese may be administered, and the still further addition of Extract of Nux Vomica or Strychnia will frequently be found advantageous; or the Citrate of Iron and Quinia, with Strychnia, may be used. The Syrup of Iodide of Iron and Manganese will also prove efficient in many cases. Tincture of Chloride of Iron has been used with benefit; so has the Bisulphite of Soda, in doses of six or eight grains every three or four hours; this last named article has proved very efficacious in some apparently hopeless cases. Spirits of Turpentine has been administered with marked benefit, in doses of half a fluidrachm or a fluidrachm, three or four times daily. When there is a torpid liver, or splenic disease, Nitro-muriatic Acid, White Liquid Physie, or Podophyllin and Quinia may be prescribed; the Nitro-muriatic Acid should not only be taken internally, but should be rubbed over the region of the liver, externally, twice a day, in a diluted state. I have used a pill composed of Berberin and Oleo-resin of Ptelea with much apparent benefit. When there is much depression of the vital powers, Wine or Brandy may be used, or the Tincture of Prickly-ash Berries.

Flatulence, pains in the abdomen, congestion of the abdominal viscera, and a tendency to constipation, may be relieved by external applications, and injections of Castor Oil, Spirits of Turpentine, and Tincture of Prickly-ash Bark, in combination. Internal hemorrhages may be arrested or lessened by the internal employment of Spirits of Turpentine, Sulphate of Iron, Kino, or Perchloride of Iron; and if the hemorrhage occur from the rectum, a properly diluted solution of one of these agents may be injected three or four times daily. I have cured a few cases of this disease with the following pill: Take of Sulphate of Iron, Cimicifugin, each, forty grains, Podophyllin ten grains, Extract of Gentian a sufficient quantity to form the whole into a pill mass; mix together, divide into forty pills, and administer one pill every two or three hours through the day. In one or two instances, Kino was substituted for the Cimicifugin. The skin was bathed daily with tepid water made slightly pungent with Tincture of Capsicum.—The internal use of Chlorate of Potassa, though it will exert no influence whatever upon the disease itself, will harden the gums when soft, and prevent their bleeding. And a gargle of a Solution of Permanganate of Potassa five or ten grains to the fluidounce of Water, will frequently be found valuable in removing the purplish appearance of the gums and

fauces ; and also being of service as a local application to the external ecchymosed patches.

The diet should be nutritious, but consisting of a spare amount of animal food ; fresh vegetables, ripe fruits, and farinaceous articles, milk, and eggs are useful ; a moderate amount of salt should be partaken of daily. The bowels should be kept regular, but not actively purged at any time during the presence of the disease. Sleep should be confined to nine hours out of the twenty-four ; moderate exercise in the open air, every day, is advisable, when the strength of the patient and the condition of the weather will permit. Cheerful society, together with a total neglect of all household or other cares and duties is recommended. In the more debilitating form of the disease, the patient should not be allowed to assume the sitting or standing posture, nor to rise for the purpose of evacuating the rectum or the bladder, as profuse hemorrhage or fatal syncope might result therefrom.

SCORBUTUS.

Scorbutus or Scurvy is a disease strongly resembling purpura hemorrhagica in many of its symptoms, though entirely different from it. In past ages it was frequently met with in military camps, in besieged towns, and especially among sailors making long voyages, but in consequence of the great improvements in the diet and hygienic rules among sailors, soldiers, etc., it is very much less common at the present day.

The theories relative to the *causes* of scurvy have heretofore been varied and conflicting. At one time it was supposed to be due to the use of stale or salted provisions ; again, a deprivation or deficiency of certain succulent and acescent vegetables containing ingredients required for the healthy constitution of the blood, was deemed a cause. According to Dr. Baly, a diet deficient in succulent vegetables, continued from three to six months, will fully develop the disease. Others have supposed that the want of vegetable albumen, or of animal casein in the food is the cause ; while still another party considers the disease due to the want of potash in the diet ; and yet another attributes its existence to a deficiency of phosphorus, sulphur, lime, and the alkalies, in the system, etc.

The potash theory originated with Dr. A. B. Garrod, and is sustained by Dr. Wm. A. Hammond and other eminent medical men ; it is, probably, the correct view, or, at all events, the one nearest to it yet presented to the profession. But, however this may be, scurvy is undoubtedly due to a deteriorated condition of the blood, resulting

in a diminution of vital power and nerve force. This deterioration may be caused by living upon an exclusive vegetable or animal diet, or by living for several months upon decomposed, scanty, or innutritious food, in conjunction, more especially, with exposures tending to depress nervous energy, as, cold and moisture, indolence, want of exercise, excessive labor, fatigue, sadness, despondency, unhealthy water, impure or damp air, uncleanness, and food deficient in acid and potash. The long-continued use of old salted meats, in conjunction with the above circumstances, is extremely apt to be followed by scurvy; indeed, the same may be said of any kind of food that possesses but little nutrient qualities, and is used in scant quantity. Whether a combination of two or more of these conditions will occasion an absence of potash in the system, has yet to be satisfactorily determined. But the treatment based upon the potash theory has proved very successful. Dr. Garrod considers the presence of potash as essential to the perfect nutrition of the muscular fiber.

The *symptoms* of scurvy develop themselves gradually; frequently, at the commencement, there will be a debility or a depression both of the mental and physical powers, the slightest exertion giving rise to fatigue and a difficult or hurried respiration. These symptoms are not always present, as it is by no means uncommon to observe cheerfulness, good appetite, considerable physical energy, and more or less activity, even for some weeks after the gums have been affected and the teeth loosened. The face, and indeed the surface generally, presents a pale or sallow and bloated appearance, and, as the disease progresses, becomes of a dusky hue; a dark ring surrounds the eyes; the appetite is deficient; the tongue is flabby and appears enlarged; the pulse is small, feeble, and generally slow, occasionally frequent, and, in the last stages, intermittent; and the skin is dry and harsh, or rough, or presenting streaks or patches resembling ecchymoses, and of various tints. Sooner or later the gums become swollen, soft, spongy, of a dark or purple color, and bleed from the slightest touch; the teeth become loose; the breath is offensive; pains of a rheumatic or neuralgic character are often experienced in various parts of the body, but more generally in the inferior extremities, chest, and back. As the disease progresses, these symptoms increase in severity, the patches on the surface enlarge, appear in greater number, and of a deeper ecchymosed appearance; the pains also augment, and are accompanied with swellings and stiffness, especially in the joints; hemorrhages occur from the nose, throat, bowels, vagina, and other mucous surfaces; hard and painful tumors appear on the limbs and jaws, which often

form fungous ulcerations; the bowels are usually constipated, but sometimes loose, with dark coagula of blood in the discharges; the urine is scanty, very dark colored, and often tinged with blood; there is a diminution of urea in the urine, a strong tendency to putridity and the development of an ammoniacal or a hydrosulphureted odor. A total absence of potash in the urine is stated to occur in all cases. Nyctalopia is frequently met with. Not unfrequently old sores or wounds, which have long been healed up, break out afresh, and eruptions upon the surface of the body frequently discharge blood, or become changed into malignant formations.

The disease is very variable, generally advancing gradually, but sometimes appearing very suddenly, and with great malignancy. The disease at sea, or on shipboard is frequently much more severe in its character than that met with on land, and this may be due to a superiority of hygienical measures in the latter instance. Death may occur from extreme prostration, from profuse hemorrhages, from diarrhea, or from gangrene of some internal organs.

The *diagnosis* is not difficult, when the peculiar symptoms, their gradual appearance, and the previous condition and hygienic deficiencies of the patient are taken into consideration. It may be discriminated from *purpura hemorrhagica*, the only disease with which it may be confounded, by the dusky, sallow hue of the skin. the greater sponginess of the gums, the indurated and painful swellings about the jaws and limbs, and the hard and unyielding livid blotches met with in scurvy, and which are absent in purpura. In purpura, the blotches are soft and impressible, and the joints are not so stiff and inflexible as in scurvy. In purpura, the blood contains a great diminution of fibrin, and is scarcely coagulable; in scurvy, the salts of this fluid, and its fibrin, are increased—the vital cohesion of the fibrin being more or less impaired, the blood corpuscles are greatly diminished, and the blood is coagulable—the albumen is increased, but probably altered in quality. Purpura is more common during the warm seasons of the year; scurvy, during the cold and moist seasons.

The *prognosis* of scurvy in its early stage is generally favorable; but in the more advanced periods, when hemorrhages are present, or dyspnœa, frequent respiration, dropsical effusions, albuminous urine, or enlargement of the spleen; or, if the disease be complicated with dysentery, pulmonary, pleuritic, or other affections, it is unfavorable, though cures have been effected even in apparently the last stage of the disease, when uncomplicated with any other malady. If an amendment occurs soon after the adoption

of suitable treatment, we may augur favorably. From a more correct understanding of the origin of scurvy, and its treatment, the disease rarely proves fatal at the present day.

The *pathological appearances* observed in scurvy, are, effusions of blood in the substance of the skin, in the subcutaneous and inter-muscular cellular tissue, in the muscles, between the periosteum and bones of the lower extremities and of the jaws. The liver may present a pale, or nutmeg appearance; the bile, pale or yellowish; the spleen, dark colored, soft, and enlarged; the lungs œdematous; and, sometimes, the mesenteric glands and kidneys will have become enlarged or undergone some morbid alteration. Traces of hemorrhage will often be observed in the mucous coats of the intestines.

The *treatment* of scurvy is more of a hygienical character; therapeutical measures being, as a general rule, required only for the purpose of overcoming urgent symptoms. A proper change in the diet; pure, oxygenated atmosphere; and a removal or avoidance of the disposing causes, are the most important among the curable measures. In addition to a moderate use of good, healthy, not diseased nor decomposed animal food, the patient should freely use fresh, succulent and acid fruits, as, oranges, lemons, limes, unripe grapes, apples, strawberries, gooseberries, pine-apples, and similar articles. Radishes, and water-cresses, eaten raw, turnips, and the sour-kraut of the Germans, are all valuable against the attacks of scurvy. The potatoe boiled, or in its raw state, grated, and eaten with vinegar, has also been found to possess most valuable antiscorbutic properties. Milk, onions, garlic, leeks, spinage, lettuce, parsley, dandelion, wild sorrel, garden cresses, rhubarb pie-plant, spruce-beer, fresh meats, etc., are all good antiscorbutics.

Now, all these articles, which are termed antiscorbutics, contain potash, and those who ascribed the cause of scurvy to a deficiency of potash in the food, as well as in the blood, having, in accordance with their theory, administered potash salts internally, found their use to be promptly followed by marked beneficial results, amendment commencing in all cases, as soon as potash appeared in the urine. In consequence of these results, the Bitartrate, Acetate, Chlorate, Carbonate, Phosphate, Nitrate, and Oxalate of Potassa have been given in cases of scurvy, and with excellent results. The Bitartrate is generally preferred, in doses of one drachm, three times a day, on account of its additional beneficial diuretic and laxative properties. Others, who attribute the beneficial effects of fruits, etc., to the acids in them, recommend, in the absence of such fruits, the use of Lime juice, Lemon juice, Citric

Acid, Tartaric Acid, etc., to which, when required, some Wine or Porter may be added.

Nitric Vinegar, so called, has been found beneficial; it is prepared by dissolving from two to four ounces of Nitrate of Potassa in a quart of Vinegar, and is administered in doses of half a fluid-ounce, considerably diluted with water, repeating the dose two, three, or four times a day.—Obstinate constipation may be overcome by Bitartrate of Potassa, taken either dissolved in Water, or in Tamarind water; or Castor Oil may be given in some Lemon juice, or in a weak solution of Citric Acid.—If diarrhea be present, an infusion of Blackberry Root, Geranium, or other astringent may be given; or, the Tincture of Kino, or of Catechu, with or without the addition of Paregoric, will frequently be of service. The Tincture of Chloride of Iron, or Solution of Perchloride of Iron, will also be found efficient in many cases, and may be used both by mouth and by injection. Similar measures may be used to check profuse hemorrhage.

Acidity of the stomach may be removed by the Compound Powder of Charcoal, or the Compound Powder of Rhubarb and Potassa.—Abdominal pains may be alleviated by opiates internally, and warm fomentations.—Sponginess of, and hemorrhage from, the gums, with a loosening of the teeth, may be removed by washing the gums freely with a solution of Chlorate of Potassa, or, with a mixture composed of equal parts of Tinctures of Myrrh, Rhatany, and Cinchona. Chewing raw potatoes, grated, either with or without the addition of Lime or Lemon juice, will be found an excellent remedy for scorbutic affections of the mouth and gums. Chlorate of Potassa used internally in conjunction with lime juice, is said to speedily restore the gums to a sound state.—Obstinate and foul ulcers may be washed with Solution of Bitartrate of Potassa, of Permanganate of Potassa, or of Chlorate of Potassa, or, with Tincture of Chloride of Iron. Or, they may be dressed with bruised Sorrel Leaves, or a Yeast Poultice,—a Cranberry Poultice will also be of benefit.—Sleeplessness will generally be removed as the patient improves in health, or it may be treated by Valerianate of Quinia, Lactucarin, Lupulin, Cypripedin, Scutellarin, Hyoseyamus, Opium, etc.

In all severe cases, and in the milder cases when anemia is present, the patient must be kept in the recumbent position, and should be cautioned against rising, or making any sudden movement or exertion, as these have been followed by immediate death from syncope, induced by putting upon the heart more work than it can

accomplish. As strength returns, moderate exercise will prove advantageous. The patient should have the surface of his body bathed daily, and also have a constant supply of air. He should be removed from a damp atmosphere to a dry one. His diet should be generous and nutritious, consisting of well-made soups, broths, eggs, milk, and mashed potatoes, at least, until the condition of the teeth and gums will admit of more solid food. For drink he may use wines, ale, porter, whey, buttermilk, tamarind water, cider, spruce-beer, lemonade, etc. The Tincture of Chloride of Iron may also be added to tonic infusions, in cases of anemia.

DROPSY.

Dropsy or Hydrops is a morbid accumulation of serum or watery fluid in the cellular areolæ, in the natural cavities, or in both, and which impedes or prevents the functions of the organs in its immediate vicinity. It is generally the result of disease in some of the important organs of the body, and is occasioned by defective absorption, excessive effusion, or both combined. The blood-vessels alone, so far as is known, are concerned in the exhalation and absorption of the watery fluid; the lymphatic absorbents having no share in the phenomena of dropsy. Dropsy may be *acute*, *sthenic*, or *active*; *passive*, *asthenic*, or *chronic*. It may also be *idiopathic*, due to some morbid condition of the blood, suppression or cessation of inordinate discharges; or, *symptomatic*, resulting from disease of internal organs, as, of the heart, liver, kidneys, spleen, peritoneum, etc. Either sex, and of all ages, are liable to dropsy, whenever the disposing causes exist. I have placed the consideration of dropsy, at this place, deeming it the most appropriate, as it appears to be a disease connected with the condition of the blood either as to quality, or, to circulation.

In relation to the *cause* of dropsy, Dr. Geo. Johnson, Professor of Practice in King's College, England, and from whom I have quoted freely in the present article, gives the following remarks:—"The explanation of dropsy is to be found in the condition of the blood-vessels and their contents. In general terms, the proximate cause of dropsy may be, 1st. A mechanical impediment to the circulation of the blood and a consequent preternatural fullness in some part, or in the whole of the vascular system; and in most, if not in all forms of dropsy, the flow of blood through the capillaries is impeded. The cause of the impediment differs in different cases. In one class of cases there is a distinct mechanical impediment to the return of blood by the veins; pressure on a venous trunk; or dis-

case of the heart, lungs, or liver. 2d. An alteration of the physical condition of the blood, and a consequent loss of that mutual relation between the blood and the vessels upon the maintenance of which depends the freedom of the capillary circulation. The morbid conditions of the blood which chiefly favor the occurrence of dropsy, are, an excess of water, with a deficiency of the solid constituents of the blood, especially of the coloring matter and albumen, as, in anemia or chlorosis, or from an imperfect action of the skin and kidneys; or, the retention and accumulation of excrementitious materials in the blood,—most frequently urea and other urinary constituents, less commonly carbonic acid, as is the case in acute renal dropsy, dropsy following scarlatina, etc. The urinary constituents being retained in the blood occasion an impeded circulation through the capillaries, and a consequent effusion of serum through the walls of those vessels.—One of the most convincing proofs of impeded capillary circulation, consequent on contamination of the blood with urine, is to be found in the hypertrophy of the left ventricle of the heart, so commonly present in cases of chronic renal disease. An analogous obstruction results from an excess of carbonic acid in the blood as proved by the experiments of Dr. John Reid.

“There is probably another cause for dropsical effusion in these cases—viz., a direct irritant action tending to cause serous effusion, but short of that which would give rise to inflammatory exudation.

“An impeded return of the blood through the veins often causes dropsical swelling of the parts beyond the seat of obstruction. Thus, the pressure of enlarged glands, or of an aneurism on the femoral or popliteal vein, or the pressure of the gravid uterus on the iliac veins, will give rise to œdema of the lower extremities. Structural disease of the liver, especially an advanced stage of cirrhosis, may greatly impede the return of blood through the portal system of veins, and the result is an effusion of serum into the cavity of the peritoneum, constituting ascites. Dr. Watson relates the case of a man who had dropsy of the head and neck and upper extremities, while the rest of the body was free from dropsical swelling, and disproportionately small. The cause of the dropsy was found to be obliteration of the superior cava vena by the pressure of an aneurism of the aorta. The larger the vein which is obstructed, the greater will be the extent of the dropsy; and when the impediment to the circulation exists at one of the orifices of the heart, the dropsy may be general over the whole body.—Now the immediate cause of the dropsical effusion in these

cases is *over-distention of the veins and capillaries, and increased pressure on their walls.*

“Experiment has shown that the transmission of fluids through membranes is in direct proportion to the *pressure* employed. Experiments by Magendie and others have also shown that while depletion of the blood-vessels by venesection quickens absorption, artificial distention of the vessels by the injection of water checks absorption and favors exhalation or the escape of liquid through the walls of the vessels.—Again, absorption is checked by a retarded movement of the blood through the vessels. ‘Fluid may be raised against gravity by directing a stream along a membranous canal which lies immersed in the stagnant fluid. The outer fluid enters the canal by endosmose, and is carried away with a speed proportioned to the velocity of the current.’ An obstacle to the return of blood through the veins therefore checks absorption and favors dropsical effusion, by causing a retarded circulation, increased fullness of the veins and capillaries, and increased pressure on their walls.—It is thus, chiefly, that valvular disease of the heart, and some forms of pulmonary disease—such as emphysema with bronchitis—cause dropsy. I shall presently show you that congestion of the kidneys, and a consequent scanty secretion of urine, are among the results of the cardiac and pulmonary disease which concur in causing dropsical effusion.”

Among the exciting causes of dropsy may be named, cold, dampness, injuries, obstructions to the circulating system, recession of cutaneous eruptions, want of proper nourishment, general debility, long-protracted fevers, frequent and excessive evacuations, as, hemorrhages, protracted diarrhea, constant use of drastic cathartics, etc., chlorosis, amenorrhea, intemperance, use of mercurials, use of pork as a diet, sudden suppression of diarrhea, dysentery, or of the excretions, etc. Some of these may give rise to the acute form of dropsy, and others to the chronic. However, the latter form is generally dependent on some pathological conditions, the principal ones of which I will now briefly refer to:

Cardiac dropsy is dependent upon some disease of the heart, which occasions a derangement in the circulation, or enfeebles it. Commonly, the heart affection has existed for a longer or shorter period previous to the dropsical symptoms. The dropsy is chronic and passive, is unattended by febrile excitement, and the blood may have undergone little or no physical change. The urine is scanty, in proportion to the degree in which the blood is impeded in its passage through the kidneys by the heart disease; indeed, a scanty secretion of urine is commonly the immediate precursor

and cause of that which is rightly called cardiac dropsy. The impediment to the circulation is in the heart, and it acts through the veins on the blood in the capillaries. In the advanced stages of heart disease, the obstructed state of the circulation often produces a congestion of the kidneys, resulting in albuminaria; but it must also be recollected that degeneration of the kidneys and consequent blood contamination frequently give rise to disease of the endocardium and valves. And it is by no means uncommon to have both the heart and kidneys implicated in many cases of general dropsy.

In cardiac dropsy the capillary obstruction is greatest in the most dependent parts, from which the blood has to ascend against gravity. And after the water has been effused into the areolar tissue, it tends to gravitate downward. For this reason, the swelling usually makes its first appearance in the feet and ankles, and gradually extends upward, being, however, greatly influenced by the position of the patient. Sometimes there will also be observed an œdema or puffiness in the face, eyelids, or superior extremities, on rising in the morning; while that in the feet and ankles is more particularly observed toward evening. This symptom may remain a considerable length of time before any symptoms of effusion in the chest, or in the abdomen, are manifested. Frequently, considerable swelling of the thighs as well as of the scrotum will be observed, and there will be more or less effusion into the cavities of the pleura, or into the lung tissue. More commonly, the effusion is met with in the thorax and abdomen, and sometimes the dropsy may be general or anasarca. When the effusion is in the thoracic cavity, the patient will require his head and shoulders to be raised considerably during sleep, and as the disease progresses he will not be able to assume the recumbent position at all. With this form of dropsy, there will also be the symptoms peculiar to the cardiac affection under which he may be laboring. (*See Cardiac Dropsy*, page 352.)

Renal dropsy is due to some disease of the kidneys, occasioning an impediment to the circulation through the capillaries. This impediment originates in the capillaries themselves, and is a result of the contamination of the blood with urinary matters. The effused fluid also contains urea, which is not present in the fluid effused in uncomplicated cardiac dropsy.—The circulation of impure blood, resulting from defective action of the skin and kidneys, is commonly attended with considerable febrile excitement, and is called acute, active, febrile, sthenic, or inflammatory dropsy. There is, therefore, an acute renal dropsy, in which the swelling

usually appears in the face, feet, and over the whole body, at the same time. The blood being contaminated, a universal capillary congestion or impediment takes place, and an active transudation through the walls of the capillaries.

Chronic renal dropsy often commences in the feet, and thence gradually extends upward, the same as in cardiac dropsy; the proximate cause of the dropsy being mainly the impoverished condition of the blood, which contains an excess of water, with a deficiency of solids, especially albumen and coloring matter. The presence of albumen in the urine, in conjunction with the other symptoms of diseased kidney, will enable us to determine renal from other dropsies; and patients with chronic renal disease are liable to become dropsical, in proportion to the abundance of albumen and the scantiness of water in the urine. Thus, we find dropsy to be almost invariably present in those cases of Bright's disease with the large wax-like and fat kidneys, which are associated with a scanty secretion of highly albuminous urine; while, on the other hand, in cases of chronic desquamative disease, a form of renal degeneration, attended with a copious secretion of urine and comparatively little albumen, there is usually no dropsy.

In most cases, anasarca or general dropsy is either *cardiac* or *renal* in its origin; but it may be due to some *pulmonary* affection, as emphysema of the lungs with bronchitis, which produces a serious impediment to the flow of blood through the lungs. In these cases an excess of carbonic acid in the blood is an additional source of impeded capillary circulation and of consequent dropsical effusion.

Hepatic dropsy is due to disease of the liver; as with the preceding forms, it may partake more or less of anasarca, but more commonly, unless associated with cardiac or renal disease, it gives rise to dropsy of the abdomen, with more or less anasarca of the lower extremities. In hepatic dropsy, there is a decided impediment to the circulation of the vena porta. This impediment may be occasioned by other lesions than those of the liver, as, dyspepsia, enlargement of the pancreas, or of the spleen, peritonitis, abdominal tumors, diseased glands, etc. These diseases may also cause a deterioration of the blood, accompanied, perhaps, by a debilitated state of the heart, which will give rise to more or less effusion, the same as is frequently observed in anemia, chlorosis, etc., where the dropsy is due to a watery blood, weakness of the heart, and consequent impeded circulation.

Dropsy is *distinguished* by several names, according to its location, thus; *adema*, is a swelling formed by effusion into the cellular tis-

sue; there is no redness, no tension, and no pain; the swelling yields under pressure of the finger, retaining the pit or impression for some time. It is distinguished from *phlegmon* by the absence of inflammatory symptoms. Œdema may be due to a disease of the heart, kidneys, or lungs, but in such cases the swelling is liable to become more or less general. When the œdema is confined to a certain locality, and is limited in the quantity of effused fluid, it is more commonly the result of some local difficulty which interferes with the venous circulation. Thus, it may occur from enlarged glands pressing upon the principal vein of the arm or leg, from crural phlebitis, from defect or impairment of the nutrition of an extremity, from an anemic or chlorotic condition, from a sprain, etc. The œdema may be limited to one limb, or it may appear in both. The presence of any local difficulty, the existence of anemia, or, of cardiac, renal, or hepatic disease, will enable us to determine the cause and the character of the œdema.

When the œdema becomes more general, the dropsical effusion is called *anasarca*, or *cellular dropsy*, which is a very common variety of dropsy. This may be limited to the inferior extremities, or it may spread over the whole body; the swelling is always regular and uniform, of a soft, doughy feel, leaving a pit or depression when pressed upon by the finger, and which slowly returns to its former fullness. Anasarca generally commences with a swelling of the feet and ankles, which is more evident in the evening, especially when the person has been standing or walking considerably; and, toward morning, when the recumbent position has been maintained for some hours, the swelling wholly or partially disappears for a time. The skin is paler than usual. As the effusion increases the swelling gradually ascends into the legs, thighs, and trunk of the body, and not unfrequently the face and eyelids appear full and bloated. Sometimes the fluid oozes through the pores of the cuticle, or raises the cuticle in small blisters, and sometimes the skin, not allowing the escape of the water, becomes compressed, hardened, and so much distended as to give the tumor a considerable degree of firmness. The effusion is much more considerable in those parts where the areolar tissue is lax. The bowels are generally more or less constipated, the skin dry, tense, and shining, the pulse natural, but usually small and weak, countenance sallow, but, in the more advanced stages, it sometimes presents a livid hue, thirst augmented, appetite deranged, and urine scanty, high-colored, giving a copious reddish deposit on standing, or, containing considerable albumen. As the disease advances, there will be a state of inactivity and sluggishness, with general debility.

When the watery accumulation has become pretty general, the vesicular and cellular structures of the lungs become affected, with difficult respiration, cough, and a watery expectoration. Anasarca may be associated with ascites or hydrothorax, when it is apt to be of a serious character, and more difficult of cure.

Ascites, or Dropsy of the Abdomen, (*See Chronic Peritonitis*), are the names applied to a collection of effused fluid in the peritoneal sac, or general cavity of the abdomen; sometimes it is found without the peritoneum, between it and the abdominal muscles, and occasionally it is contained in sacs formed upon and connected with some of the viscera, as the liver (*hydatids*), or ovaries (*ovarian dropsy*), forming what is termed "encysted dropsy." Ascites is met with next in frequency to anasarca. It is often preceded by an impaired appetite, sluggishness, dryness of the skin, cough, oppression at the chest, scanty urine, and constipation. Occasionally ascites may be preceded by anasarca of the lower extremities.

Dropsy of the abdomen presents at first a slight enlargement of the inferior part of the abdomen, together with a disagreeable feeling of fullness, and some tenderness when pressure is made; the enlargement gradually advances as the effused fluid accumulates, until the whole abdomen becomes uniformly swoln and tense. As the swelling progresses, the difficulty of breathing usually increases, being worse when the patient lies down; the face is apt to be pale and bloated; there is more or less thirst; the stomach and bowels, in most cases, perform their functions with tolerable regularity, but sometimes they become deranged, with nausea, flatulence, colic pains, and a sense of weight in the abdomen; the pulse is variable; the urine scanty, thick, high-colored, with reddish deposits on standing.

Ascites may be *detected* by the dull sound elicited on percussion; and by the practitioner placing one hand upon one side of the abdomen, while the patient is sitting or standing, and striking on the opposite side with the finger tips of the other hand, which will give rise to a distinct fluctuation, readily felt, and frequently obvious to the ear. The tympanitic resonance of the bowels will also be found to vary according to the position of the patient, as these organs usually float on the upper part of the effused fluid.

Dropsy of the abdomen may be detected from *tympanitis*, as, in the latter malady there is a clear tympanitic sound on percussion, and no fluctuation can be perceived. From *ovarian* or *encysted dropsy* by the indistinct and limited fluctuation; by observing that instead of the uniform swelling of the abdomen found in ascites, only one side, or some particular part of the abdomen is more protuberant than the rest; and by a change of position effecting no

change in the resonance of the bowels by percussion ; adhesions from peritonitis will prevent the ascites from presenting its proper symptoms, and they may be so limited and indistinct as to be mistaken for ovarian dropsy, but the history of the case, from which we may learn the existence of a previous peritonitis, or some tubercular disease of the peritoneum and mesenteric glands, together with the constitutional symptoms present, will materially aid in the diagnosis. In ascites the general health suffers more than in ovarian dropsy, and there is also more liability to detect cardiac, renal, or hepatic disease. From *dropsy of the womb*, by observing that the tumor is confined to the region of this organ, and, as it increases, somewhat resembles the shape of the pregnant womb ; it yields upon pressure ; there is a less marked sense, or an entire absence of fluctuation, and the urine is but slightly diminished, if at all. From *dilatation of the bladder*, by evacuating this organ by means of a catheter. From *pregnancy*, by the absence of fluctuation, and the usual signs of pregnancy ; in dropsy the countenance is pale and sickly, and œdema of the feet and ankles are present, which is not the case in the early months of pregnancy. Pregnancy and ascites may co-exist, which renders the diagnosis very difficult, especially in the earlier months, before ballottement, etc., can be obtained. (See *Hydrocephalus*, or *Dropsy of the Brain*, page 168.)

Hydrothorax, or Dropsy of the Chest, are the terms applied to an accumulation of serum within the cavity of the pleura ; this form may exist alone, but generally prevails as part of a more universal dropsy. Its injurious consequences are due more to its mechanical compression than to any peculiar quality which it possesses, as the lungs are frequently reduced in size by its pressure, and even the heart may be displaced. At an early period of hydrothorax there will be an oppression and difficulty of breathing experienced, proportioned to the extent of the effusion, and these symptoms will be augmented on every sudden or uncustomary exercise, or when the body is in a horizontal posture ; and when there is effusion in both pleural cavities, the breathing is still shorter and laborious. There is an inability to lie on the side of the chest where effusion does not exist, and as the disease progresses the patient is compelled to sleep more or less in a sitting posture. There are frequent shiverings ; a short, dry cough ; sense of uneasiness or heaviness at the lower extremity of the sternum ; paleness of the complexion ; feeble and irregular pulse ; confused and disturbed sleep, with unpleasant dreams and sudden startings ; palpitations of the heart ; and occasional syncope. As the effusion increases, the face, lips, and hands present a livid or mottled aspect ; anasarca swellings of the feet

and legs occur; thirst increases; a sensation of numbness in one or both arms, extending from the cardiac region toward the insertion of the deltoid muscle is frequently complained of; the eyes present an anxious stare; and the urine is scanty, high-colored, giving reddish deposits on standing. Sometimes the patient can distinctly perceive a sensation of fluid in motion, or making certain sudden changes in the position of the body.

The continued accumulation of fluid is marked by intolerable difficulty of breathing; the patient being obliged to remain in the erect posture, with his mouth open, and his body leaning toward the side in which the effusion is greatest, while he incessantly manifests the greatest anxiety for fresh air. The face and extremities become swollen and cold; a cold, clammy sweat occurs upon the face and upper part of the body; drowsiness, coma, or delirium, occasioned by the difficult transmission of the blood through the lungs, and want of sleep, frequently attend the latter periods of hydrothorax, and from the same cause the expectoration is sometimes bloody. Death may take place suddenly; in some cases it is preceded for a few days by a spitting of blood; but more commonly the patient dies gradually from suffocation or apoplexy, the first being the result of the increased pressure of the accumulated fluid on the lungs; the second being the result of pressure of the dark, venous blood on the brain, not unfrequently accompanied with serous effusion on the surface of this organ, or in its ventricles. Occasionally, hydrothorax ends in general dropsy, and which may, indeed, accompany it from the beginning.

When hydrothorax is due to an inflammatory attack, the effusion is commonly on one side only; when it is the consequence of some lesion of the heart, kidney, or liver, the fluid is effused into both pleural cavities. Upon inspection, the affected side will frequently be found enlarged and round; the intercostal spaces become effaced at the lower parts of the chest, as they are extended by the gradual divergence of the ribs, and the intercostal muscles will be more inactive than those of the opposite side. An abnormal position of the heart may be readily discovered by observing the point at which the apex of the organ is seen to beat. An absence of the natural vibrations usually communicated by the voice to the walls of the chest (vocal fremitus), characterizes the presence of effusion in a pleural cavity, and which may be ascertained by placing the hand on the side of the thorax containing the fluid. Mensuration will detect a difference of size between the two sides of the chest, the affected one being increased in circumference. Percussion will elicit a dull or perfectly flat sound, to an extent proportionate to the

quantity of effusion present ; by altering the position of the patient the character of the percussion sounds will vary, according to the altered level and depth of the fluid under examination. Auscultation will, at first, give a muffled or tubular inspiratory murmur, the weakness of which will vary according to the amount of fluid present ; when the disease is well marked, there will be an entire absence of the normal murmur toward the base of the chest, (especially in its lower or back parts), where the fluid is naturally accumulated to a great extent. Sometimes a tubular sound may be heard, more distinct about the angle of the scapula. Friction sounds are not present in hydrothorax. If the fluid be not in too large quantity, ægophony may be heard ; though this may exist in hepatization, when there is no pleural disease. When the hydrothorax is due to cardiac or other visceral lesions, dropsical effusions in other parts will co-exist.—The diseases with which hydrothorax may be confounded are, chronic pleurisy, pericardial effusion, abscess in the walls of the chest, enlarged spleen or liver, a tumor within the chest, pneumo-thorax, and emphysema ; in cases of doubt, great care should be taken to arrive at a correct diagnosis, and especially in cases where the operation of paracentesis thoracis is about to be performed.

Chronic dropsy is almost always symptomatic, and rarely idiopathic, and to determine the disease upon which it is dependent may frequently be readily effected by the symptoms which manifest themselves. But often it becomes a difficult matter to do this, and the practitioner will then have to proceed carefully in his investigation, before he can satisfy himself that the effusion is due to anemia or watery blood, or to lesion of the heart, liver, kidneys, lungs, etc. And in such investigation a thorough knowledge of all the symptoms pertaining to these several lesions will prove a most valuable and important aid. (*See Chronic Hydrocephalus*, page 168, and *Hydropericardium*, page 348.)

The *prognosis* of dropsy depends upon the nature and extent of the disease of which the dropsy is a symptom. Some forms of dropsy are readily curable, as, the acute dropsies, and those due to certain changes in the blood, as, in chlorosis, anemia, etc., and those dependent upon renal disease, in its early stage. When the disease to which the dropsy is owing is incurable, or of long standing, the dropsy may sometimes be relieved, but never cured. Thus, a chronic dropsy, dependent upon long-standing renal, cardiac, lung, or hepatic disease, is seldom, if ever curable, or, at least, not until the organic disease is cured. The location of the effusion has also an influence upon the prognosis ; when in the cavities of the body,

it is more unfavorable than when seated in the areolar tissue. Ascites is, as a general rule, less difficult of removal than hydrothorax. Young and otherwise good constitutions usually admit of cure more readily than the infirm, and those advanced in years. Local dropsies almost always disappear with the removal of their cause. Dropsy following the exanthema, hemorrhages or other profuse discharges, or, an improper or innutritious diet, is generally curable.—In hydrothorax, or effusion into the pleural sac, we may determine the increase or decrease of the liquid, by percussion, which gives a flatness of sound along the level line of the fluid, as well as below it. For this purpose a nitrate of silver mark may be made along the line indicating the level, at different periods of examination.

The *pathological appearances* met with in dropsy are various, according to its locality. The fluid itself will vary in color, being dark colored and turbid, sanguineous, limpid, yellowish, greenish, or brownish; it may be whey-like and turbid, as when there has been considerable vascular action in the seat of the effusion, or it may contain lymph, mucous, or albumen, or a mixture of these, frequently in the form of shreds, or flocculi, etc. Generally the fluid is of a faint-yellow color, more or less turbid, of specific gravity 1010 to 1025, of alkaline reaction, containing more or less albumen, chloride of sodium, and, if the kidneys are diseased, urea; if fatty matter be present, cholesterin may usually be found in it.

The serous membranes may be thickened and opaque, either indurated or softened, often presenting indications of previous inflammatory action, as, coagulable lymph, old adhesions, etc.; the serous surfaces may be covered wholly or partially with a reticulated lymph, with granulations, or tuberculations. In the cellular tissue, the areolæ may be distended by the effused fluid, the cells enlarged or ruptured, the intermuscular tissue hardened, the fibers of the true skin separated so that the fluid may penetrate its denser parts, and sometimes the cellular tissue may be softened and plastic.—In addition to these, will be observed the appearances common to the renal, cardiac, or other disease, upon which the dropsy depends.

In the *treatment* of dropsy two indications are to be fulfilled, 1st, to remove the cause of the dropsy; and 2d, to remove the accumulated fluid from the system. The first object may be attained by the adoption of those measures necessary for the removal of the disease or condition occasioning the dropsy, and which are given under their respective heads; and, as a general rule, when the disease is cured the dropsy disappears. When the dropsy is

from a poor and watery condition of the blood,—as, in chlorosis,—nutritious diet, fresh air, moderate exercise, and chalybeates, will improve the quality of the blood, and the dropsy becomes cured. But this is not always the case, as the effused fluid may remain, and require to be removed by the appropriate treatment for the dropsy. Again, the disease may be incurable, and then the removal of the accumulated fluid from time to time may afford temporary relief, and prolong the patient's life. And again, the active and continued measures adopted for the removal of the dropsy, will sometimes be followed by a cure both of the original disease and the dropsy.*

A very important class of agents to aid in removing the accumulated fluid in dropsies, are Hydragogue cathartics. There are several of these which have been recommended, but the one I generally prefer is the following: Take of powdered Jalap three

*“In cases of *acute renal dropsy*, the urine is at first scanty and of morbid quality, being often high-colored from admixture with blood, always albuminous, and usually containing casts of the kidney tubes. The scanty secretion of urine is the cause of the dropsy, and the secretion of urine is scanty because the flow of blood through the kidney is obstructed and the structure of the gland changed, the tubes being filled with desquamated epithelium and with blood and fibrin which have escaped from the gorged Malpighian vessels. Now observe what happens during the progress of cure in a case of this kind. The patient we will suppose to be placed in circumstances favorable for recovery; he is confined to bed; has a scanty diet; the loins are dry cupped, or mustard and linseed poultices are applied there; and means taken to excite the secretory action of the skin and bowels, and thus to lessen the work of the kidneys. Soon the secretion of urine begins to increase, until, in the course of four or five days, perhaps, the quantity of urine, which at first had been less than half the natural amount, becomes three times as great as the standard quantity, no diuretic medicine of any kind having been given.

“The explanation of this spontaneous diuresis appears to be this: During the acute stage of the renal disease, the constituents of the urine, both solids and liquids, have accumulated in the blood, and have thence been effused into the areolar tissue and into the serous cavities. Now urea itself is a most powerful diuretic; and no sooner is the inflammatory congestion of the kidney removed, and the freedom of the renal circulation restored, than the urea exerts its natural diuretic action on the kidney. The copious diuresis thus induced speedily removes the accumulated urinary solids and liquids from the blood, the areolar tissue and the serous cavities into which they had been effused, and so the dropsy is cured.

“This abundant flow of urine occurs without aid from diuretics or drugs of any kind. I have seen it occur while bread pills alone were given as a placebo. Stimulating diuretics, such as squills, or cantharides, or turpentine, are injurious by increasing congestion of the kidney. The best diuretic in such cases are means which tend to lessen the congestion of the kidneys; counter-irritation over the loins, especially by dry cupping; hot-air baths and diaphoretics, purgatives, and a scanty diet.” (G. Johnson.)

drachms, Bitartrate of Potassa six drachms, powdered Elaterium from one grain and a half to six grains; mix thoroughly together, and divide into twelve powders. One of these powders is to be administered every six hours. The Elaterium frequently occasions nausea or vomiting, which may generally be overcome by the addition of three or four grains of Capsicum to each dose. When copious watery discharges are produced, the use of the powders may be discontinued; or, if required, may be still continued every six hours but without the Elaterium. Other hydragogue preparations may be employed, as, a mixture of Podophyllin one-fourth or one-half of a grain, Bitartrate of Potassa twenty grains; mix for a dose, which is likewise to be repeated every six hours. The powdered root of the Large Flowering Spurge (*Euphorbia Corollata*) is a very valuable hydragogue in dropsy; it may be given in doses of fifteen or twenty grains, repeating it every day or two; it induces copious watery evacuations, and sometimes gives rise to emesis, which may be checked by the administration, with each dose, of a grain or two of Extract of Hyoseyamus. On account of the greater solubility of the tartrate of potassa, or, the tartrate of potassa and soda, it is preferred by many, in the above preparations, being substituted for the bitartrate. Another hydragogue, sometimes used by practitioners, is composed of Elaterium one grain, Compound Extract of Colocynth two scruples, Extract of Hyoseyamus twelve grains; mix, and divide into twelve pills, of which one may be taken every twelve or twenty-four hours. The strength of the patient must be taken into consideration in the administration of these powerful cathartics; and the hydragogues should be repeated only once, twice, or thrice a week, according to his strength and ability to bear catharsis. If great debility and prostration follow the use of the hydragogues, the strength of the patient must be properly sustained by stimulants and nourishment. Croton Oil, in doses of a minim, repeated sufficiently often to act freely upon the bowels, may also be used with advantage; it does not produce the debility which follows the use of elaterium, but, while it lessens the quantity of effused fluid, it also appears to augment the action of the absorbents. It may be given on sugar, in emulsion, in pill form with crumb of bread, or, in combination with Soap and Compound Extract of Colocynth. The fresh bark of the root of *Sambucus Nigra*, scraped, and the juice obtained from the scrapings by pressure, is also an excellent purgative in dropsy, in doses of from a teaspoonful to a tablespoonful; it occasions no inconvenience. Probably, the root bark of *S. Canadensis* will answer equally as well.

A very excellent cathartic may be administered in cases where the tongue is smooth and red, with irritable stomach and bowels. tenderness on pressing over the epigastric region, and where the ordinary hydragogues are not retained upon the stomach, as follows: Take of Indian Hemp (*Apocynum Cannabinum*) two ounces, Blue Flag Root, Queen of the Meadow Root, each, one ounce; make three pints of infusion; or, three pints of tincture with equal parts of Holland Gin and Water, of either of which a tablespoonful may be given every two hours, until the bowels are acted upon freely. Or, the Alcoholic Extracts of these articles may be used, in pill form.

To promote absorption of the effused serum, increase the secreting action of the kidneys, and improve the condition of the blood. I believe there is no preparation so generally efficacious as the Compound Infusion of Parsley, which should be used during the intervals between the cathartics. For the same purpose, Iodide of Potassium has been highly extolled, and will undoubtedly prove useful in serofulous and tuberculous habits, and in dropsy accompanying albuminaria, and yellow liver—where the liver or kidneys are enlarged, and owe their peculiar appearance to interstitial deposition of fatty and morbid fibrinous matter.

For a constant drink, it will be better for the patient to use some diuretic infusion or decoction, as, equal parts of Dwarf Elder and Juniper Berries; or, equal parts of Spearmint, Parsley Root, Elder Bark, and Indian Hemp Root; or equal parts of Queen of the Meadow Root, Dwarf Elder, and Indian Hemp. The infusion or decoction of either of these compounds may be drank pretty freely whenever diuresis, or quenching thirst, is desired. Meadow Sweet Herb (*Spiræa Ulmaria*) in decoction, is useful in some cases of dropsy, proving actively diuretic, and causing an absorption of the effusion without producing debility, or lowering the circulation; so is an infusion of Ampelopsis Quinquefolia. Other diuretics may be employed, as, *Asclepias Syriaca*, *Verbascum Thapsus*, *Pyrola Umbellata*, *Juniperus Virginiana*, etc. When the urine is albuminous, the free use of an infusion of Canada Snakeroot, will frequently be found of service.

When the effused fluid has been carried off, the Compound Infusion of Parsley should be used daily for several weeks, in order to prevent farther effusion; resorting to the preceding measures, whenever symptoms of a returning effusion are manifested. And, the treatment for any organic disease which may exist, must be persistently adhered to; omitting it only occasionally, when active

measures are being adopted, as, the administration of hydragogues, etc.

In anasarca of the extremities, as the fluid is absorbed and carried off, the limbs should be bandaged their whole length as tightly as the patient can bear comfortably, renewing it once or twice daily, particularly in the morning when the swelling has somewhat diminished from diffusion of the fluid, owing to the recumbent position. In ascites, as the water is carried off, a broad bandage must be worn around the abdomen, sufficiently tight not to be uncomfortable, and gradually increasing its pressure as the enlargement decreases. This mechanical support is a very important measure, as it enables the tissues to regain their natural tone and vigor, after the extreme and enfeebling distension to which they have been so long subjected. If the bowels be kneaded or shampooed by hand, two or three times a day, after the fluid has commenced to disappear, much benefit will be derived from it, and, particularly, if, after each shampooing, we apply over the abdomen with considerable friction, a liniment composed of equal parts of Oils of Juniper, Sassafras, Cajeput, and Spearmint.

The surface of the body and limbs should be bathed daily with a weak alkaline solution, using considerable friction in drying. And, in anasarca of the legs, friction with a coarse towel or flesh-brush should be made use of on every renewal of the bandage, also, applying, where stimulation is required, a mixture of two parts of Olive Oil, and one part of Tincture of Capsicum. In hydrothorax, the Hot Air Bath will be very useful, when the strength of the patient will permit; employing it once or twice a week.

Stork's-bill Geranium (*Erodium Cicutarium*), a plant introduced into this country, and growing along the Oneida lake-shore, New York, and in other sandy locations, is an excellent diuretic and tonic, and has proved very efficacious in renal and hepatic dropsies, even when hydragogues and other agents had failed. Two ounces of the dried plant are placed in three pints of boiling water, and simmered down to two pints; the dose of the strained decoction is three or four fluidounces, repeated four times a day. (*Dr. W. A. Smith.*)

"In some cases of chronic renal dropsy, diuretics may be given without risk, but too often without much benefit in the way of removing or lessening the dropsy. Diuretics are more frequently successful in cases of cardiac dropsy, when the kidneys are free from disease.—In the treatment of cardiac dropsy, while we endeavor to remove the fluid by diuretics and by purgatives, which

excite copious watery discharges from the bowels, it is desirable to do what we can to sustain the power of the heart by nutritious food, stimulants, and tonics, little or nothing can be done to repair a damaged valve, but much may be done to strengthen the muscular walls of the heart, and thus enable it to overcome the impediment to the flow of blood, and the consequent tendency to dropsy which a diseased valve occasions. When other means fail to remove the dropsical accumulations, we may often afford great temporary relief, and prolong life, sometimes, for a considerable period, by mechanical means—by tapping the abdomen, for instance, in a case of ascites; by acupuncture or incisions through the skin of the legs for the removal of anasarca;” and by paracentesis thoracis in hydrothorax. (*G. Johnson.*)

Tonics will indeed be found very valuable in chronic dropsy, and will sometimes effect cures even where diuretics prove useless, as, for instance, in anemic conditions, where there is excessive debility and no organic disease, in which cases the Tincture of Chloride of Iron, with or without Quinia, will be beneficial. In cases of enlarged spleen, the following mixture will often prove advantageous: Take of Syrup of Hypophosphite of Iron four fluidounces, Hypophosphite of Quinia one drachm; mix. The dose is a fluidrachm to be repeated three or four times a day. In some cases of chronic renal dropsy, I have derived considerable benefit from the stimulating diuretic effect of Oil of Turpentine, given in doses of ten drops, and repeated three or four times a day, gradually increasing the dose, according to the effect produced and the progressive condition of the patient; but its action must be watched, as in some cases it will aggravate the disease, from the renal irritation it is apt to occasion.

In ascites from chronic peritonitis, occurring in strumous habits, Syrup of Iodide of Iron with Cod Liver Oil, has effected cures; the syrup should be omitted when diarrhea is present, and opiates and astringents be given. (*See Chronic Peritonitis.*) In cases of passive albuminous anasarca, especially those following the exanthematous diseases, Tannin, in doses of thirty to sixty grains per day will often give rise to abundant diuresis; so will urea, in doses of one-third of a grain, given in sugar, and repeated three times a day—the diuresis in the latter case will not be manifest until after six or eight grains have been taken. An infusion of Elder Bark in Sherry Wine, taken in wineglassful doses three or four times a day, has been found valuable. I have had great success in the treatment of dropsy following scarlatina, by the following course; Take of Nitrate of Potassa one scruple, Bitartrate of Potassa two

scruples, Infusion of Parsley Root twenty-four fluidounces; mix. For a child from five to eight years of age, the dose is half a fluidounce every hour, so that the whole twenty-four fluidounces shall be taken up in the course of forty-eight hours. This must be repeated daily until the dropsical swelling has disappeared, and a free diuresis been produced, which will vary from three to seven days, when its use must be omitted, and an infusion of Parsley Root, or some other diuretic be freely administered, together with some Tincture of Chloride of Iron. Should there be, at the same time, a thick white coat on the tongue, or other symptoms of gastric acidity, an alkaline solution should also be given, as, a Solution of Bicarbonate of Potassa. And to sustain the strength of the patient, wine or other stimulant may be administered as required; and, when all swelling has disappeared, some tonic Wine Bitters should be used for a few weeks thereafter.

The diet, exercise, etc., must be suited to the peculiar circumstances of the patient, to his strength, to the condition of the blood, and to the character of any existing organic lesion. For the operations required to discharge the accumulated fluid, and thus afford temporary relief, the reader is referred to works on Surgery, in which they are described.

ANEMIA.*

Also termed Oligæmia, Spanæmia, Hydroæmia, Poverty of the

*CANCER is an affection not included within the scope of this work, belonging, as it does, to the department of surgery; yet, as some of my readers may desire to know what kinds of treatment have been pursued for its cure, I will give a list of the principal ones that have fallen under my observation. As may be seen, some of them appear to be active enough to remove almost anything in the form of normal or abnormal tissue, but I wish it to be distinctly understood that I neither recommend them nor vouch for their efficiency.

1. Take a piece of soft leather somewhat larger than the size of the cancer, and in this cut an orifice the exact size and shape of the ulcerated part, as near as possible. Upon the remaining rim of leather, spread some White Turpentine to render it adhesive, and then apply it around the ulceration in such a manner as to have the inner opening exactly fit the margin of the ulcer. Fill up this internal opening upon the surface of the ulcer with fine Brass Filings, and cover this with another piece of leather, upon the marginal circumference of which some White Turpentine has been spread, in order that it may adhere. Every day or two remove this cover, cleanse the ulcer with Castile Soap-suds, dry it, and apply more Brass Filings, cover as before, and so proceed. Whenever the first rim of leather becomes loosened from the skin, apply more White Turpentine to the margin. This "rots out" the cancer with but little or no pain, leaving a simple ulcer to heal. It is supposed to act galvanically from the copper

Blood, etc. This disease is a condition directly opposite to that of plethora, which consists, not as the word "anemia" indicates, in an absolute decrease of the quantity of blood in the system, but in a deficiency in the normal number of its red globules. The normal

and zinc in the brass; but as some arsenic is usually present in brass, I am disposed to look upon this as the active agent. I know of two cases in which this has effected apparently permanent cures.

2. Take of Solution of Persulphate of Iron, Aqua Ammonia, each, four fluid-ounces, Water a sufficient quantity, say half a pint; mix, and allow the mixture to stand until there is no longer a precipitate; filter through strong muslin, express to remove as much water as possible, and, before the resulting Hydrated Sesquioxide of Iron has dried, add to it enough fresh Lard to form an ointment. When required for use, to four ounces of this ointment add from ten to twenty grains of finely powdered Arsenic, according to the size of the cancer, or the pain, etc., it produces, and rub thoroughly together. A portion of this ointment is to be applied daily, until the whole malignant growth is reduced to a slough, and until a needle can be passed into it in various parts, as far as the healthy tissue, without causing pain or tenderness. Then the slough may be removed by applications of Slippery Elm Poultices. Heal the simple ulcer left by frequently dressing it with Solution of Tannic Acid, and Elm Poultice containing Tannic Acid, which heals the part without granulation and without leaving a cicatrix; being careful at each dressing to remove any "roots" that may be observed on the surface of the ulcer. If any malignancy is observed at any part, the ointment must be re-applied over it, and treated as before. Should an erysipelatous redness occur around the cancer, or should much pain be produced while using the ointment, the quantity of arsenic must be reduced. If the cancer is not open, the cuticle may be removed by Cantharidal Collodion, before applying the ointment.—This is stated to have effected numerous cures of cancer without pain, and "taking it out by the roots," and I know of several in which apparently thorough cures were effected; but in large, extensive, or long-standing cancerous ulcerations, it generally fails. A cure by this method requires from two to six months, as the process is a gradual one. Some persons who have built up a considerable reputation for curing cancers, employ, in conjunction with this treatment, a Solution of Potassio-tartrate of Iron, or Fowler's Solution internally.

3. Take of finely-powdered hard wood Soot two ounces, Belladonna Ointment two ounces; mix thoroughly together, and then add of finely-powdered Arsenite of Copper from sixteen grains to an ounce. The quantity of Copper salt to be added will depend upon the sensibility of the patient, as no pain must be caused by the application; the quantity must also be regulated by the extent of surface of the cancerous ulcer. A portion of this ointment spread upon cotton batting is to be applied to the ulcer daily.

4. Triturate thoroughly together a drachm, each, of Sulphate of Iron, Sulphate of Copper, Nitrate of Potassa, and from five to ten or twelve grains of Arsenic. Mix the compound with enough White Turpentine to form a plaster, of which a small quantity spread upon lint or linen rag is to be applied upon the cancer, repeating it every day or two, and continuing its use until the disease has been removed by it. After which heal the simple ulcer left by the ordinary means, or by applications of the following ointment, viz.: Take of Rosin eight ounces,

medium of these globules in the blood is 127 out of every 1000. These may be lessened to 113, and even still lower, and not be incompatible with health; but when they reach 80 and below, then we have the disease under consideration, and its seriousness will be

Reeswax four ounces, Lard six ounces; melt these together, strain, and add of finely-powdered Subacetate of Copper half an ounce.

5. File down a silver twenty-five cent piece, dissolve it in Nitric Acid two fluid-ounces, and then add enough powdered Sulphur to form a plaster. Apply this to the cancer, repeating the application every two hours. Three or four applications are said to be sufficient to destroy the cancer, which may then be removed by "poulticing."

6. Mix together Red Oxide of Iron one ounce, Arsenic one scruple. When to be used, mix a small portion with the yolk of an egg, and spread it thinly on oil silk or bladder. If the cancer has not ulcerated, the skin must be removed before applying the above, by means of Cantharidal Collodion. The application should be renewed every day until a slough is formed, which may be removed by poultices. If too much pain is caused, remove the plaster for a time, and apply anodyne cataplasms.

7. Make a strong ley of the ashes of Red Oak Bark, and evaporate this to the consistence of a thin extract. Cover the cancer with this, and allow it to remain on an hour; then remove, and apply a plaster of common Tar, which may remain on for a couple of days. Then, after removing the dressings, should any portion of the cancer remain, re-apply the caustic alkaline plaster, and pursue the same course as before, repeating it until the cancer is cured. The simple ulcer left may be healed in the ordinary way. This is very painful.

8. Take of Red Oxide of Iron, Animal Charcoal, each, one ounce, Digitalis, Sulphur, each, half an ounce, Balsam of Canada a sufficient quantity to form a thin plaster. Spread a small quantity of this upon a linen cloth, apply it over the whole surface of the ulcer, and cover with a common tar plaster. Repeat these applications daily, until the cancer is destroyed; no pain follows its use.

9. Take of recent Marygold Flowers and Leaves, recent Red Clover Flowers and Leaves, Bloodroot, Digitalis, each, in coarse powder, half an ounce, Carbolic Acid four ounces, Glycerin eight ounces; mix the articles together, and allow them to stand fourteen days. Apply some of this, on lint, to the cancer every day. Said to be also useful in lupus and other cutaneous diseases.

10. Take of Extract of Arrow Wood (*Viburnum Dentatum*), Extract of Marygold Flowers and Leaves, Extract of Red Clover, and Extract of Wild Indigo Leaves and Bark of Root, each, equal parts; mix, and form a plaster, which apply on linen to the ulcer, cleansing it daily. Internally, use the following: Take of Salt of Tartar one ounce, Cream of Tartar four ounces, Water two quarts; mix. The dose of the solution is a wineglassful three times a day.

11. Take of Sulphate of Zinc, Sulphate of Copper, each, one ounce; Sulphate of Morphia, one drachm; mix thoroughly together. To use it, mix a sufficient quantity with white of egg, and apply. It is quite painful.

12. To an Aqueous Extract of recent Sassafras Bark, add a few drops of Nitric Acid, until a froth or foam is formed; spread this on a piece of lint, and apply twice a day. Previous to each application, wash the ulcer with a mixture of equal parts of brandy and honey. This will not act on the healthy tissue but only on the cancer; and when this is destroyed, heal the ulcer with,—Sweet Oil

in proportion to the amount of diminution of the globules of the blood. Anemia is, therefore, due to a clear, watery, viscid state of the blood, in which it forms, if at all, a small, soft, diffuent clot; or, in other words, the blood contains an excess of fluid, and a diminution of red corpuscles and iron. Poverty of blood is the most appropriate term for it. Chlorosis is a well-marked form of anemia in females, associated with amenorrhea.

The exciting *causes* of anemia are various; it is frequently produced by copious losses of blood; imperfect nourishment; continued profuse discharges; unhealthy diet; glandular diseases; impure air; excessive fatigue; want of rest; malarious atmosphere; privation of sunlight; and whatever exhausts or depresses the vital and nervous powers. The existence of an anemic condition may permit disease to occur, which would not have done so under opposite

one pint; Beeswax, one ounce; melt together, and when nearly cold, add Nitric Acid, half an ounce. Apply this once or twice a day, at the same time using the above wash between the dressings.

Chromic Acid,—Oxalate of Copper or of Tin, dissolved in a solution of Oxalic Acid,—Sulphate of Zinc,—Chloride of Zinc,—Inspissated juice of Sheep Sorrel,—Solution of Binoxalate of Potassa, etc., have all been recommended.

Fell's cancer plaster is prepared as follows; Take of Chloride of Zinc three ounces, finely-powdered Bloodroot, one ounce, Bayberry Wax half an ounce, Extract of Conium, Watery Extract of Opium, each, three drachms. Mix together and form into an ointment. Remove the skin by Cantharidal Colloid, and apply this to the raw tumor; when it forms an eschar, cut lines or furrows in this, about half an inch apart, being careful not to injure the healthy tissue, and then continue the application of the plaster. He uses this alternately every twelve hours, with the following: Take of Glycerin two drachms, Spermaceti Ointment four ounces, Iodide of Lead two scruples—mix, and form an ointment. Apply this over the ulcer every alternate twelve hours. In conjunction with these, he gives the following pills internally: Take of pulverized Bloodroot two scruples, Iodide of Arsenic four grains, Extract of Cicuta four scruples; mix, divide into eighty pills, of which one pill is a dose, to be repeated three times a day.

Another agent said to be useful in cancer is the following: Take of Manganic Acid, Arsenious Acid, each, half an ounce; Charcoal two drachms; Extract of Belladonna six drachms; mix together, and form a plaster. Carbolic Acid has recently been found to destroy cancer cells under the microscope; when applied to the parts affected it is said to relieve pain very much, destroy the fetor, and to bring about healthy action. It may be used in combination with Citric, or Acetic Acids. It has been applied to cancer and other malignant formations in the following combinations:—1. Take of Carbolic Acid forty-five minims, Alcohol half a fluidounce, Water one pint; mix. 2. Take of Carbolic Acid one part, Pyroligneous Acid of 8°, four parts, Water fifteen parts; mix. It may also be variously combined with Acetic Acid, Glacial Acetic Acid, Solution of Citric Acid, Sulphate of Zinc, Sulphate of Iron, etc. Perchloride of Iron, used locally and internally, has been found very effectual in some cases of malignant growths.

circumstances; while, in other cases, its presence is a symptom or indication of various lesions. It is almost always present in an advanced stage of malignant diseases, and is frequently found associated with several chronic maladies.

The principal *symptoms* of anemia are, a waxy paleness of the surface, and pallor of those mucous membranes adjacent to the skin, as the lips, tongue, inside of the mouth, conjunctiva, etc.; the pulse is feeble, small, slow, irregular or intermittent, but easily accelerated upon mental or physical excitement; languor; debility; bowels irregular, flatulent, and often acidity of stomach; appetite deficient; a sense of sinking, of suffocation, or of syncope, with more or less palpitation on exertion, and, in some cases, upon assuming the erect posture; respiration short, hurried, oppressed, and sometimes gasping; vertigo; tinnitus aurium; nausea, or vomiting; and œdema of the lower extremities, especially about the ankles. Not unfrequently a very obstinate headache will be present. The greater part of all these symptoms will be present in well-marked cases of anemia. The urine in anemia is clear and pale, contains less urea, uric acid, and fixed salts than the normal urine, is of low specific gravity 1010 to 1018, and, as a general rule, deposits no sediment, unless associated with some functional or organic lesion.—Auscultation will detect a peculiar murmur or blowing sound in the jugular vein, which is often co-existent with distinct carotid impulse, which may be interrupted by pressing upon the vein above the location of the stethoscope, and which is increased by any cause that accelerates the flow of blood through the jugular vein. This sound is termed *bruit de soufflet*, *bruit de diable*, or *venous hum*. Auscultation over the heart will detect a murmur at its base, and occurring with the systole.

Anemia may not only be a symptom of, but often gives rise to, hysteria, epilepsy, syncope, palpitations, nervous tremors, diarrhea, gastralgia, colic pains, worms, hemorrhages, as well as atrophy and softening of several of the internal viscera. It may terminate life by symptoms of exhaustion; by a convulsion; by symptoms of effusion on the brain, or in the pleural or pericardial cavities; and, in very unfavorable cases, the patient may have a fatal attack of syncope on suddenly assuming the erect posture.

Dr. Wilks has recorded several cases of a new disease, which he has termed *anemia lymphatica*. The essential features of the disease are, the most extreme pallor of anemia, enlargement, with often pain of one or more of the various groups of lymphatic glands, either internal or external to the body, as, the cervical, mediastinal, bronchial, lumbar, and inguinal, etc., and a peculiar

morbid condition, with occasional enlargement of the spleen; the last depending upon the deposition of an opaque, white, lardaceous material, in isolated masses, or diffused throughout the substance of the organs, and resembling bacon-rind. The disease has been mistaken for scrofula from the glandular enlargements present; may occur at any age, and after two or more years, or as soon as the thoracic and abdominal glands become involved, prostration gradually takes place, followed by death. The disease, thus far, has invariably proved fatal. There is a deficiency of red globules in the blood, and the "anemic bruit" is present; œdema or anarsaca may also exist. (*See Leucocythemia.*)

The *prognosis* of anemia, as a general rule is favorable, except when it is complicated with other diseases, and then much will depend upon the nature of the accompanying lesion, and whether the anemia is its cause or effect. Frequently, when anemia exists as an effect, an attention to the condition of the blood, improving it, will permit a cure of the original disease by treatment which had previously proved of no avail. A long-standing anemia may give rise to lesions which are incurable, even though the original malady, the state of the blood, may be greatly improved. If to the pale urine of an anemic or chlorotic patient, we add one-fourth its bulk of strong nitric acid, and then boil it, and it assumes a red or deep mahogany hue, it is an indication that the blood corpuscles are being too rapidly consumed, that the life's blood is oozing away by the kidneys—as shown by the excess of urohæmatin (red blood-coloring matter) in the urine. In these cases, although fed well, the patient loses flesh, because the blood-coloring matter is fast passing away.

In some of these obscure cases, if we boil four ounces of the urine with one ounce of nitric acid, so as to set all the coloring matter free, and then, when cold, put the urine into a six ounce vial along with an ounce of ether, cork it, thoroughly shake it, and let it stand for twenty-four hours,—the ether, having taken up the urohæmatin, will be found solidified into a red, tremulous currant jelly-like mass, which may sometimes be cut with a knife. In the worst form the urine is neutral or even alkaline. Sometimes the nitric acid will merely change the color of the urine to yellow, while sulphuric, or hydrochloric acid will develop the red color. Excess of urohæmatin is an unfavorable symptom, though, when properly treated and taken in time, most cases can be cured. (*G. Harley.*)

The *pathological appearance* of those who die from anemia, are, more or less paleness of the tissues of the various organs, espe-

cially the heart and blood-vessels; in long standing cases, the heart may be atrophied, with softening of its substance. Serous infiltrations may also be observed in some of the cavities, and in the cellular tissue.

The *treatment* for uncomplicated anemia, consists in the administration of some preparation of Iron, with nourishing diet, well-regulated exercise, and attention to the bowels, kidneys, and skin. And it must be recollected that the red corpuscles require a greater length of time for their restoration, than any of the other constituents of the blood. But iron alone will not always prove successful, or, it may produce benefit to a certain point at which the disease subsequently remains stationary. In such instances, other additional agents will be required. Very frequently, the addition of Manganese to the Iron will promptly act, effecting a regeneration of the blood, and a permanent cure. Pills of Carbonate of Iron and Manganese; Pills of Iodide of Iron and Manganese; or, Syrup of Iodide of Iron and Manganese, will prove very efficacious. And, if there should be, at the same time, a great deficiency of nervous power, Alcoholic Extract of Nux Vomica, or Strychnia, should be administered in conjunction with the Iron, or Iron and Manganese preparations, or, the Citrate of Iron and Quinia with Strychnia may be preferred.—Tannic Acid, administered internally, will frequently be found to improve the blood in anemia, hence, the efficacy of alterative syrups, etc., in which the barks, roots, etc., contain tannic acid.

If diarrhea be present, Sulphate of Iron, Tincture of Chloride of Iron, Perchloride of Iron, etc., may be given. If much nervous irritability and wakefulness, Valerianate of Iron, or, the iron may be combined with a sedative, and, in many cases, where there is an excessive nervous impressibility, Hydrocyanic Acid, or the Oil of Bitter Almonds will be found of great utility; however, I prefer the latter as being less liable to decomposition than the acid.—If struma be present, Iodide of Iron, Bromide of Iron, Elixir of Iron and Cinchona, and similar preparations may be used. In many instances, especially where there is nervous debility with diminution of mental activity, Hypophosphite of Iron, with or without the addition of Hypophosphite of Soda, or of Potassa, will be found very valuable; or, Procter's Compound Syrup of Hypophosphites, may be used. The Pyrophosphate of Iron and Soda has also been highly recommended as a valuable preparation, not liable to be precipitated, or transformed into an oxide when taken into the stomach; it is given in solution, is easy to administer, rapidly absorbed, and does not produce fatigue to the digestive organs.

These same agents may also be employed in cases of excess of uro-hæmatin in the urine.—Chlorosis will not only require ferruginous preparations, but also uterine tonics to overcome abnormal conditions of the uterus, as, Alcoholic Extracts of Black Cohosh, Blue Cohosh, Aletris, Senecio, etc.; aided frequently by Iodine, Bromide of Potassium, or other alteratives, together with counter-irritation, and all the necessary measures required to combat various abnormal symptoms that may present themselves.

When the anemia is complicated with functional or organic lesions, these must be combated with the proper treatment for them, in conjunction with the means used to overcome the anemic condition of the patient.

LEUCOCYTHEMIA.

This is a morbid condition of the blood, consisting in a marked increase of the white globules, which imparts a reddish-gray tint to the blood, the same as is observed in the blood of the splenic vein, which, in health, always contains a great excess of colorless corpuscles; it was first discovered by Professor J. H. Bennett, of Edinburgh, Scotland, who subsequently gave to it its present name, meaning, "white cell blood." Men appear to be more liable to this affection than women, though no age or sex is wholly exempt from it.

The *causes* of leucocythemia are still a matter of speculation. It exists in combination with disease of the spleen, liver, and lymphatic glands. The spleen, in this affection, appears to be more commonly diseased than the other organs, being enlarged to such a degree that its weight may be found to vary from one to eight or nine pounds. It is also met with in affections of the thyroid gland; though it must be recollected that hypertrophy, malignant or non-malignant disease of these several blood-glands, may exist, without the presence of leucocythemia. This morbid condition of the blood can not, therefore, be characteristic of any special affection, but constitutes a symptom of various lesions. Anemia differs from leucocythemia in consisting of a diminution of the red corpuscles, while the latter consists in a great increase of the white corpuscles of the blood.

The *symptoms* are paleness or dinginess of the surface, and of the conjunctiva, a cachectic appearance, with more or less enlargement of the spleen, liver, lymphatic glands, especially those of the axilla, the neck, the abdomen, etc., and of the thyroid gland. Bronchocele is sometimes accompanied with leucocythemia. The

enlargement of the spleen, and liver, will give rise to a tumor which in some cases may extend from the ribs to the groin, and from the spinal column to the umbilicus. The tumor is hard, dull on percussion, and painful on pressure over one or several parts of it. In connection with these, there will be several of the following symptoms: diarrhea, dysentery, hurried and difficult breathing, giddiness on assuming the erect posture, ringing in the ears, lassitude, more or less debility, sometimes emaciation, slight transitory pains in the abdomen, or in the hypertrophied glands, the anemic bruit or bellows murmur may be heard over the heart and large vessels, epistaxis, or hemorrhage from the gums or from internal organs, and sometimes œdema or ascites. The appetite may remain good, the bowels continue regular or become costive, the tongue clean or furred, dry and brown, pulse small and weak, from seventy-five to one hundred, and the urine healthy, or, especially when ascites is present, scanty, turbid, and loaded with urates, or phosphates.

But in order to satisfactorily determine the character of the affection, we must not rely upon these symptoms only, but must institute a microscopic examination of the blood itself, a drop of which may be obtained by pricking the finger with a needle; it should be placed immediately upon a glass slide, covered with thin glass, and be examined under a power of at least three hundred diameters. The colored and colorless corpuscles will be seen rolling confusedly together, but the latter will be greatly in excess; instead of being in normal amount, about one to fifty of the colored, they will be found varying from one to ten to one to two. The colored globules usually collect together in rolls, while the colorless ones fill up the intervening spaces. If a drop of acetic acid be added to the drop of blood, it will render the cell wall of the colorless corpuscles very transparent, bringing into view the nucleus, consisting of a single round or oval body in some, and, in others, consisting of two, three, or even four nuclei, each having a central depression or shadowed spot, and, in some instances, the nuclei will be crescentic or horseshoe form.

The *prognosis* in well-marked cases of leucocythemia associated with distinct glandular enlargements, is decidedly unfavorable; and, though in the less-marked cases, considerable improvement may take place under treatment, it is still doubtful whether any permanent results have been obtained. The patient may die suddenly, even when we are congratulating ourselves upon his apparent improvement, or he may die in a state of delirium, or from hectic fever and gradual exhaustion. In some cases, treatment has so far

improved the condition of the patient as to prolong his life for several years.

The *pathological appearances* observed in leucocythemia, are, grayish or cream-colored clots in the heart and large veins, exhibiting great numbers of white corpuscles, and usually more or less crystals (hematoid) of rhomboidal form, yellowish, and soluble in acetic acid. Distension of some of the large veins; simple hypertrophy of the spleen or liver; or enlargement of the lymphatic glands in the groin, axilla, bronchii, mesentery, etc. Sometimes the liver will be found cirrhotic, or cancerous; and when the lymphatic glands are enlarged, they are soft, present a granular-whitish appearance when cut into, and yield a copious turbid fluid on pressure, which is crowded with corpuscles. Occasionally these glands will be indurated, containing calcareous, tubercular, or cancerous deposits. In a few cases, Peyer's glands, and the thyroid gland have been found hypertrophied. These are the chief appearances, although other abnormal conditions may be met with according to the particular lesion or lesions with which the leucocythemia may be associated.

The *treatment* of this affection consists in the administration of preparations containing Iron, Manganese, and Nux Vomica, in conjunction with Bromide of Ammonium, Iodide of Ammonium, Hypophosphite of Ammonium, or, Nitrate of Ammonium. Indeed, the constitutional treatment named under Anemia, appears to be likewise proper in leucocythemia. For the hypertrophied condition of the organs, Nitro-hydrochloric Acid, White Liquid Physic, Podophyllin, and a nutritious but moderate diet, are the means to pursue; aided by currents of electro-magnetism through the hypertrophied organs, and hypodermic injections of a dilute solution of Chloride of Gold and Soda in their immediate neighborhood. A pill composed of Oleo-resin of Blue Flag, Oleo-resin of Prickly-ash Bark, Baptisin, each, one grain, and Peroxide of Iron, a sufficient quantity to form a proper consistence for a pill, may be given for a dose, and be repeated three or four times a day, or so as to fall short of purgation; and this, in conjunction with Procter's Compound Syrup of Hypophosphites, will frequently be found a very valuable treatment. The preparation referred to under the treatment of Chronic Peritonitis, composed of Blue Flag, Black Cohosh, Soluble Pyrophosphate of Iron, Glycerin, Water, etc., may frequently be of immense benefit; in two cases, I used it with most excellent results.

Exercise in the open air, but not to fatigue, and frequent bathings and frictions of the skin, are also necessary; and, in cases of diar-

rhea, or hemorrhages, astringents will be required, especially those from among the ferruginous preparations; or, Tannic Acid, Gallic Acid, etc. The principal indications being to remove or palliate any urgent symptoms, or complications, and to support the vital powers.

CACHEXIA AFRICANA.

Negro Cachexy is a disease of the nutritive functions, presenting chlorotic symptoms, but which differs from Chlorosis, as males and even children become attacked with it. It is peculiar to the southern and West Indian blacks.

It appears to be *caused* by grief, despondency, harsh treatment, improper or unhealthy food, severe labor, bad nursing of children, indolence and inaction, etc.

The *symptoms* are a depression of spirits, in which the patient indulges, and for the indulgence of which he seeks solitude, he appears drowsy, is inactive, greatly enfeebled, and has neither the inclination nor the ability to labor. The least exertion produces hurried or difficult breathing; the appetite becomes lost; there is a constant gastric pain; gastric acidity, with a desire to eat absorbents or alkalies, as, earth, chalk, etc.; palpitation; pallid countenance; tongue coated white, and its body pale, with dark, ink-spots upon its surface; the conjuncture white and shining; the skin cold and of an olive hue; œdema of the face, lids, and extremities; white or clay-colored stools; scanty urine; and a small pulse, more accelerated toward the close of the day. If there is an effusion of serum in the abdomen or in the chest, breathing can be performed only in the erect position. With the advance of the disease the lymphatic glands become indurated and inflamed; the liver enlarged and hard; the red globules of the blood are diminished; and sudden death occurs, by asphyxia.

In the *treatment*, a generous and nutritious animal diet must be pursued; and the body should be frequently bathed with a mixture composed of Salt one drachm, Tincture of Capsicum half a fluid-ounce, Vinegar, and Water, each, two fluidounces. Daily moderate exercise is necessary; frictions over the surface; warm clothing; and regularity of bowels. Cheerfulness should be encouraged. Pork, damp, cold, or night air, and fatiguing exercise, must all be avoided.

To restore the blood to a normal condition, chalybeates should be given, as, Iodide, Carbonate, or Pyrophosphate of Iron, Reduced Iron, etc. When the urinary organs become torpid, stimulating

diuretics will be required, as, the Compound Infusion of Parsley, Compound Infusion of Trailing Arbutus, etc.

Negroes frequently present very strange and peculiar symptoms, which they attribute to poisoning or witchcraft, and many of which cannot be accounted for. I have treated many such cases successfully, by the administration of one or two teaspoonfuls of a mixture of powdered Rock Salt two parts, Capsicum one part; the dose should be given every two or three hours, and be accompanied with external means to cause a profuse perspiration. This course should be repeated every day or two, until a cure is effected.

CHRONIC DISEASES OF THE RESPIRATORY SYSTEM.

THE diseases of this system, include those of the nares, larynx, trachea, and lungs, and which are very common to this country, both in the acute and chronic forms. The many methods that have been recently devised for correctly diagnosing these diseases, and for enabling the practitioner to more directly inspect and make applications upon the tissues of the affected parts, have rendered them much more amenable to treatment than has been the case in past years. These methods are, examinations by means of the rhinoscope, the laryngoscope, percussion, auscultation, etc.; and, for the following remarks upon the laryngoscope, I am chiefly indebted to its discoverer, Czermak; to Dr. Gibb, who has devoted much attention to the use of the instrument, and has also published a valuable work on Diseases of the Throat and Windpipe; to Dr. G. Johnson, etc.

The LARYNGOSCOPE consists of a small mirror of steel, speculum metal, or glass, attached to a flexible metallic stem, which is fixed into a handle of wood, ivory, or ebony. The mirror, of which each practitioner should possess several, is of various forms and sizes, being circular, quadrangular with the angles rounded off, oval, or elliptical, and from three or four lines to an inch and a half in diameter. In consequence of the rapidity with which steel mirrors tarnish, glass and metallic mirrors plated with gold or silver, are preferred; though, if attention be paid to the proper cleaning of the steel ones, immediately after use, they may be preserved for a long time. The laryngeal mirror is inclined upon the stem at an obtuse angle, which, however, may be altered to any angle whenever this is desired. The angle at which the mirror is placed upon the stem, should be such that when inserted beneath the palate, it reflects the light thrown upon it into the larynx, and at the same time reflects back an image of the larynx to the eye of the observer. A

circular or quadrangular mirror, an inch in diameter, is the most convenient for general use.—Whenever the laryngeal mirror is to be used, it should be warmed over a spirit lamp, before introducing it into the mouth, in order to prevent the dimming of its surface by the patient's breath; exposing, not the back, but the surface only of the mirror to the flame, and estimating its temperature by applying the back of it to the cheek or temple, in preference to the hand. The mirror should not be heated too much, as it will burn the patient's mouth, and, if it be a glass one, will have the silvering spoiled; the temperature, however, should be as high as can be conveniently borne by the person to be examined.

To use the mirror requires an illumination of the throat, and this is effected by reflecting the light from the sun, or from a lamp into the throat by means of a concave mirror or reflector, three or four inches in diameter, and possessing a focal distance of ten to fifteen inches, and which is fixed either in front of the right eye of the examiner, between the two eyes, or upon the forehead; the latter position is generally preferred. When artificial light is employed, another reflector should be placed behind the lamp. The reflecting mirror to fix upon the forehead, and the laryngeal mirrors can be had at any surgical instrument maker.

The person to be examined should be seated on a chair, to the right of a table, with the lamp near his left elbow, and a little behind him. His mouth should be on a level with the nose or eyes of the examiner, and the flame of the lamp should be on a level with, or even a little higher than the operator's eyes. The light should be brilliant and steady. The operator, sitting directly in front of the person to be examined, arranges the reflector on his forehead, or in front of his eye, etc., as he prefers, and, desiring the patient to open his mouth as wide as possible, and to incline his head forward and slightly upward, directs the rays of light from the reflecting mirror through the mouth to the back of the pharynx. This illumination having been regulated, the warmed laryngoscope is now passed rapidly over the tongue, but without touching either it, the teeth, lips, or back part of the pharynx, though it is gently applied against the middle of the soft palate and uvula, in order to elevate them. The light from the reflecting mirror striking upon the laryngoscope, the patient quietly breathing as usual, and the laryngoscope being placed at the proper angle, the parts will be seen in the following order,—it being borne in mind that the objects as seen in the laryngeal mirror, are reversed from before backward;—the back or postero-inferior portion of the base of the tongue with its large follicles: the fossæ at its base, or valleculæ,

also called the glosso-epiglottic sinuses, being situated on each side of the frænum or glosso-epiglottic ligament, and becoming shallower as they proceed laterally,—these sinuses are very apt to be diseased; the epiglottis,—its apex and laryngeal surface; the posterior part of the cricoid cartilage, with its mucous membrane; the pharynx; the arytenoid cartilages with their apices; the cartilages of Santorini; the aryteno-epiglottic folds, or ligaments, with the cartilages of Wrisberg in the negro; vestibule of the glottis; superior thyro-arytenoid ligaments, or false vocal cords; ventricles of Morgagni; and the true vocal cords, or glottis.

The operator should practice the introduction of the laryngoscope with either hand, resting the little finger of the hand employed upon the cheek of the patient. If sunlight be used, the patient should sit with his back to the sun, and the rays should not be concentrated to a focus, lest a heat sufficiently great to burn the larynx be produced. The measures recommended will, of course, have to be modified by the image we obtain, and by the circumstances; thus, the laryngoscope may have to be advanced or withdrawn a little, or bent at a more or less obtuse angle, or a change may be required in the position of the lamp, or in the position and attitude of the patient, etc. For applying remedies, or performing delicate operations, the mirror must be introduced with the left hand, so that the right may be employed as circumstances require; and the patient must be instructed to manipulate his own tongue while the operation is being performed.

If the laryngeal mirror comes in contact with the tongue especially, or with the back part of the pharynx, which are the most sensitive parts within the mouth, cough, retching, dyspnoea, and other unpleasant symptoms may be produced, so that it is absolutely necessary to avoid contact with these parts in order to secure a satisfactory examination. But some persons can not keep the tongue advanced and flattened or depressed, but will throw it upward toward the roof of the mouth, just as the mirror is being introduced, and thus present a serious obstacle to the examination. This is generally due to a nervousness on the part of the patient, and is sure to be made worse by any petulance in, or cross remarks of, the operator. This may be overcome in several ways; by depressing the tongue with a spatula; by having the patient himself lay hold of his tongue with a napkin or handkerchief held between his thumb and forefinger, and gently but firmly hold it outward and downward, at the same time opening his mouth as wide as possible, and strongly calling his will into action that he may not thrust the tongue upward nor close the mouth. In some instances it will be

necessary to educate the parts, as it were, in order to allay nervousness and irritability; this can be effected by having the patient practice before a looking-glass, opening the mouth wide and keeping it so, while he flattens and depresses the tongue, pulls it forward, and frequently places it in contact with foreign bodies; the physician should also attempt the introduction of the laryngoscope every day or two. Several trials of this kind will eventually overcome the difficulty.

In all cases where it is required to examine the throat and fauces, using the tongue spatula, no satisfactory examination can be made, unless we can persuade the patient to open his mouth and breathe quietly through the mouth, and *not through the nose*, while the spatula rests on the tongue, and to effect which the patient's nose may be closed. He should not hold his breath, nor breathe more slowly or rapidly than usual, but should be requested to breathe quietly and as usual. If inspiration be effected through the nose, the tongue is raised and closes the mouth so that the pharynx can not be seen; if it be effected through the mouth, the back part of the tongue falls or remains down, and the uvula is somewhat elevated, so as to present a clearer view of the back part of the throat. A broad spatula should always be employed, carrying it as near to the root of the tongue as possible, without exciting much irritation; and the lips should be widely expanded, so as to permit the light to freely enter the throat.

An unusual sensibility of the fauces from inflammatory congestion, may be overcome by directing the patient to hold a lump of ice in his mouth for ten or fifteen minutes before the examination, and as the ice melts to swallow the cold water. Or, twenty drops of Chloroform placed on a handkerchief and inhaled, will quiet the most irritable throat without producing discomfort or drowsiness. Prof. Semeleder applies a solution of Morphia in Chloroform to the fauces, and to the internal wall of the larynx, by means of a curved brush, in order to lessen the sensibility of these parts, and permit the use of the mirror, as well as the introduction of instruments within the larynx. In some cases an astringent and soothing gargle, used for a day or two, or anodyne vapors directed upon the fauces will be found sufficient.—Generally, the tongue will come more under control after two or three sittings. And it will be found that the repeated introduction of the laryngoscope at intervals of a day or two, will have the effect of lessening the sensibility of the throat, so that after a short time the most sensitive throat becomes tolerant to the instrument.—An examination of the larynx may become difficult or impossible, from enlargement of the ton-

sils, elongated epiglottis, or where it is so pendent as to prevent the light from being thrown beneath it, and also where there is a great contraction of the arch of the epiglottis. More failures in examining the larynx occur among children than among adults.

Antolaryngoscopy, or where one can examine his own throat, requires the aid of different reflecting mirrors, etc.; Czermak's autolaryngoscope is well adapted for this purpose. But it is not my design to enter into an explanation of this; those of my readers who have some curiosity to examine their own vocal apparatus are referred to the several works on this subject already issued.

Laryngoscopy, as well as rhinoscopy, requires a good anatomical knowledge of the parts about the nose, throat, and larynx. And the student can become quite proficient in laryngoscopic examinations if he will educate himself to the operation, by examining the throats and vocal cords of all his male and female friends, old and young, as far as possible; studying their shape, position, color, and movements in health.

The parts observed by the laryngoscope present the following peculiarities in health: the *epiglottis* is an oval, or sub-triangular shaped cartilage, of a pale salmon, buff, or crust-of-bread color, convex below, and somewhat concave above, situated at the base of the tongue, usually nearly erect, projecting about half an inch high, immediately above the entrance into the windpipe, forming an angle of from 60° to 80° with the upper part of the laryngeal aperture: in some throats it can be seen by the unaided eye, by depressing the tongue. Its mucous membrane is more or less injected, though sometimes pale, with some clearly defined red vessels ramifying over its surface. The *glosso-epiglottic fold*, or ligament, is a vertical fold or frenum between the tongue and the epiglottis, in the median line of the body, composed of elastic tissue, and readily seen with the laryngeal mirror. The epiglottis is also attached to the hyoid bone by means of a thin ligament, the *hyo-epiglottic*. It is also connected, at its apex or inferior extremity, through a long, slender, elastic cord, to the receding angle or pomum of the thyroid cartilage, immediately beneath the median notch, and above the attachment of the vocal cords; this cord is termed the *thyro-epiglottic ligament*. On every side, anteriorly, laterally, and posteriorly, the epiglottis is connected with the tongue, pharynx, hyoid bone, and arytenoid cartilages by means of folds of mucous membrane, which are named individually according to their particular attachments. The most important of all these are the *aryteno-epiglottic folds*, within which are muscular fibers, which help to draw down the epiglottis with or without the cognizance of the will.

When the *glosso-epiglottic* fold, from cold, cynanche, follicular disease, etc., becomes lax, losing its power of contraction to draw up the epiglottis, the surrounding mucous membrane being deficient in firmness and elasticity, and discharging a quantity of fluid from its follicles, the epiglottis will be more or less pendent, sometimes to such a degree as to render a laryngeal inspection impossible; it is important, therefore, always to observe its degree of erection or pendency. Again, the *aryteno-epiglottic folds*, with their muscular fibers, may often act so spasmodically as to keep the epiglottis permanently backward. The elasticity of the epiglottis may also be permanently destroyed in many cases, occasioning a greater or less degree of pendency, and giving rise to a thick, guttural voice; again, it may be, at the same time, in a congested condition, occasioning dyspnoea, a sensation as if some foreign body were lying at the back of the tongue, constant efforts to clear the glottis, and to swallow, and a fear of suffocation.

When we desire to render the field of vision in the interior of the larynx and of the trachea broader, we must separate the epiglottis from the posterior wall of the pharynx; this may be accomplished by requesting the patient to utter the sounds *ah* or *eh*, so as to give a convenient position to the base of the tongue. The complete emission of the vowel *e*, elevates the base of the tongue to the point of entirely covering the laryngoscope; but it does not do so when we only desire to pronounce the vowel, *without* actually pronouncing it,—the mere attempt sometimes suffices to bring about the wished-for result.

In health, the interior of the larynx above the glottis is of a pale rose color. The *glottis* is a fissure, running in an antero-posterior direction and which is formed by the true vocal cords; it is of triangular shape, but may be oblong, lanceolate, elliptic, lozenge or barrel-shaped. It may be extremely movable, or but slightly so. If the patient pronounces the syllable *ah* or *eh*, in a prolonged or short, or high falsetto note, the glottis will be seen to close, and the vocal cords vibrate with the impulse of the expired air. If the above syllable be successively repeated a few times, the glottis will be seen to open for inspiration, and close during the utterance of sound. The latter is the test of integrity, and permits an appreciation of the amount of approximation which the vocal cords undergo.

As soon as one desires to utter a sound, the two arytenoid cartilages raise themselves in the fold of mucous membrane which covers them, and approach one another the whole length of their internal surfaces with surprising mobility and complete freedom,

drawing the vocal cords together, rendering them more or less convergent, more prominent, and closing the glottis with great energy. By attention and practice the investigator may master the movements of the arytenoid cartilages, accelerating, retarding, or arresting them, as he may desire.

In quiet breathing, the glottis remains widely open. When the glottis is contracted or closed during pronunciation, the arytenoid cartilages perform very rapid and independent movements. During the emission of sounds from the chest, or of a shrill voice, the epiglottis assumes a different position, and is more or less distant from the arytenoid cartilages. Contraction of the aryteno-epiglottic muscular fibers draws the epiglottis backward, and applies its base or cushion, and then its posterior and inferior surface, upon the closed vocal cords. At this instant the base of the tongue covers all up, and nothing further is seen.

The *vocal cords*, or inferior thyro-arytenoid ligaments, are distinguished by their whitish-yellow, or white color tinged with a shade of gray, from the neighboring parts of a reddish color; their pearly white margins, which vibrate with surprising rapidity with the impulse of the expired air, have a brilliant, somewhat metallic, appearance. Corresponding to their attachments will be observed four yellow spots, indicating the vocal processes, two being anteriorly, and two posteriorly; the latter are larger than the anterior, and are of much value in judging of the movements of the vocal processes, and the tension of the vocal cords.

The *subglottis* is of a pale fawn color which shades off in the trachea into a drab; the thyroid and cricoid cartilages, where not otherwise covered, are white with a tinge of red; the rings of the trachea appear of an almost white color through the transparent membrane, with reddish inter-membranous portions; the parts more deeply situated appear dark. In some persons, the arytenoid cartilages are of a yellowish pink, and those of Wrisberg, (almost always present in negroes), when present, have a yellowish tinge like a small abscess.

RHINOSCOPY is an examination of the posterior recesses of the nostrils, and of the pharyngo-nasal recess, and is much more difficult than laryngoscopy. The laryngeal mirror is used in this, in the same manner as in laryngoscopy, with the exception that its reflecting surface is turned upward. The uvula and soft palate are generally drawn forward, out of the way, by a small hook, which may be attached, on a movable joint, upon the stem of the

laryngoscope. Sometimes the examination can be made without the use of the hook, by applying a small mirror on either side of the uvula behind or below the velum, and which is much the best method when it can be effected, as the hook is apt to excite a contraction of the palatē, causing it to completely obstruct the view by drawing upward and backward; this drawing is also effected by a deep inspiration, and may be avoided during the examination by directing the patient to breathe quietly.

The parts that are brought into view by a rhinoscopic examination are, the posterior openings of the nasal fossæ, the three turbinated bones, the septum narium, the roof of the pharynx, and the orifices of the Eustachian tubes. Of course, in order to obtain a view of all the parts named, the mirror will require to be inclined or directed in the proper position.—A rhinoscopic examination should always be made with delicacy and gentleness.

The appearances of the healthy parts seen by a rhinoscopic investigation are as follows: the septum narium is a prominent object, generally of a vivid pink color; the turbinated bones have a pale pink and drab color; but when congested, the blood-vessels are distinctly seen, and have a bluish tinge. The oval trumpet orifices of the Eustachian tubes are usually of a pale yellow color.

In all cases, after an examination of the larynx or nose, the laryngeal mirror should be immediately wiped with a soft sponge moistened with warm water, and then dried and thoroughly rubbed with a soft piece of chamois, in order to prevent it from becoming tarnished. And steel mirrors should always be carefully inspected from time to time, occasionally rubbing them with whiting, soft rotten stone, or the soft, silky feeling part of the ashes of cannel coal, which will not scratch the softest metal. When stained or tarnished they are not fit for use until they are reburnished.

The instruments required in laryngoscopy and rhinoscopy for applying remedies, are, variously curved brushes for the larynx and nose; laryngeal electro-pole, fumigation tube, insufflation tube, porte-caustic, sponge-carrier, and brush; Weiss' fluid pulverizer; Dr. Elsberg's nebulizer, an excellent and cheap instrument for forming spray to be inhaled into the air passages; other spray instruments; Matthieu's irrigator; curved forceps; scarificators for œdema of the larynx; laryngeal syringes; glass bottle with accompanying sliding rod to apply fluids to the nasal cavities by hydrostatic pressure; curved bougies; bistouries; long curved

scissors; Gibb's laryngeal ecraseur; tongue depressors; small sponges; linen napkins, etc.

The remedies employed are, acetic acid; tannic acid; benzoic acid; concentrated nitric acid; chromic acid; tincture of belladonna; tincture of aconite; tincture of sheep laurel; tincture of gelsemium; tincture of oil of stillingia; tincture of geranium; tincture of Indian hemp; tincture of rhatany; tincture of capsicum; solution of atropia; solution of morphia; solution of strychnia; solution of quinia; solution of perchloride of iron; balsam of Canada; glycerin; glycerin one ounce, tannin two drachms, as a useful topical astringent; glycerin one ounce, muriate of morphia, fifteen to sixty grains, as a soothing application in irritable larynx; glycerin and alum; glycerin and perchloride of iron; glycerin and strychnia; glycerin and a solution of nitrate of silver; very dilute carbolic acid; chloroform; alum; sulphate of zinc; chloride of gold and soda; concentrated decoction of golden seal; spirits of turpentine; chloride of zinc; chlorate of potassa; permanganate of potassa; tincture of myrrh; nitrate of silver; iodine; hydrochlorate of ammonia; aluminated sulphate of copper; aralia spinosa; swamp milkweed; camphor; black cohosh; citric acid; horseradish; oil of erigoron; oil of erechthites; oil of lobelia; geraniin; alum root; balsam peru; cod liver oil; sanguinarina; common salt; mullein; tincture of St. John's wort, etc. These are used in the solid, liquid, or gaseous form, single, or in various combinations, and, by inhalation, or by direct application with some one of the instruments referred to above, especially with the brush.

. "I yet feel it a duty to remark upon the possibility that the larynx may get too much of local treatment. The laryngoscope has brought this organ so completely within our reach that we are all exposed to the temptations of being too meddlesome. We may be too apt to forget that a structural disease, strictly limited to the larynx, may yet be constitutional in its origin, and require a plan of treatment based upon the recognition of that fact. If we can avoid the error to which I have here alluded, the introduction of the laryngoscope will be an unmixed good both to ourselves and to our patients, and it will soon be acknowledged to be one of the most valuable additions that have ever been made to our means of diagnosis and treatment." (*Geo. Johnson.*)

In the investigation of diseases of the thoracic organs, as, the lungs, bronchii, pleura, etc., other methods are had recourse to as

aids in forming a diagnosis; though some physicians rely *almost wholly* upon the evidences which these methods develop, to the exclusion of other signs,—this is entirely wrong, the measures about to be referred to, are indeed valuable, but they should not have an exclusive importance attached to them, nor be relied upon too implicitly,—they should always be received in conjunction with all the other symptoms present, before concluding upon our diagnosis. In no other way will we be enabled to arrive at correct and satisfactory conclusions. No one physical sign has any value in determining particular disease; it may inform us of a morbid alteration existing in a tissue or tissues, but it does not make known the disease producing or accompanying this alteration. Besides, there is no pathological state which is invariably accompanied by any series of physical signs. A safe diagnosis can only be based upon the conjunction of evidence from many sources. The methods referred to are, inspection, palpation, mensuration, succussion, percussion, and auscultation. These modes of examination may be employed in the investigation of the diseases of various other parts of the body, but it is more especially in diseases of the thoracic organs that their utility stands pre-eminent; and, in order to render them available in the diagnosis of disease, the physician must be well versed in them, he must know the particular value of each of them, and must have had an experience in them at the bedside,—for it is here only that they can be learned, and not from books or diagrams.

For the purpose of localizing the physical signs as accurately as possible, it has been the custom to form a topography of the chest by artificially mapping it out into regions; and the boundaries adopted have been different with different observers. The simplest arrangement, and that which is more frequently followed is the one dividing the surface of the thorax into anterior, posterior, and lateral regions. These regions are again subdivided; the anterior, into—the *clavicular*, one on each side; the *subclavian*, one on each side; the *mammary*, one on each side; the *infra-mammary*, one on each side; the *upper sternal*; and the *lower sternal*. The subdivisions of the posterior region are on each side, the *acromial*; the *scapular*; the *inter-scapular*; and the *dorsal*. Of the lateral region, on each side, are the *axillary*; the *lateral*; and the *lower lateral*.

Many other arrangements may be found, each differing, as already stated, from the rest; and any one of these may be adopted by those who desire it, but they had better all be rejected. The simple fact that there are so many arrangements destroys the use of any one—because the only object in making them must be to

facilitate the accurate description of the site of the disease. But as there are numerous plans of topography, the divisions of which differ in their limits, no accuracy of description can be obtained by their use unless we first state, in each case, the author of the arrangement followed; and then it will be necessary to give the definitions, otherwise it will be intelligible only to those who are acquainted with the same author; and at last, some further method of division must be adopted, to indicate how much, and what portion, of any region is affected.

It is of the greatest importance that the terms of science shall be clearly intelligible to as large a number of persons as possible; and hence, whenever it is practicable, they should be based upon universal facts. In the present instance, we have a basis of this kind in the *obvious anatomical points*, such as the clavicle, its two ends and middle; the scapula with its angles and spine; the sternum with its divisions; the ribs with their numbers, their angles, their cartilages, etc.; the axillæ; the nipples; the intercostal spaces with their numbers; and the spaces above and below the bones mentioned. These anatomical points, which are familiar to all, may be taken as the landmarks or fixed points from, and to which, measurements may be made with any degree of accuracy.

In examinations of the chest, the patient should be placed in such a *position* that its walls may be rendered firm and tense, while, at the same time, the patient remains comfortable, and the physician can go through with the examination without any inconvenience. In an examination of the anterior parietes, the patient should sit, as erect as possible, upon a chair or stool, opposite to a good light, allowing the arms to hang loosely by the sides, the head being thrown somewhat back, and the upper part of the body covered with a thin piece of muslin, or else entirely uncovered. When the lateral regions of the chest are to be examined, the patient should be directed to place the hand of the side under examination upon the back part of his head, which raises the arm out of the physician's way, also, to incline the upper part of the body over a little to the opposite side.

In examining the back, he should fold his arms across his breast, lean well forward, and hold down his head.—In some instances the patient may stand, if able to do so, during inspection, palpation, mensuration, and percussion.—If his strength or condition will not permit him to sit in a chair, he may be examined while sitting up, or even while lying, in bed, but this will render it more inconvenient to the practitioner, who will have to observe a little more care in conducting the examination. The room must, during the

investigation be kept quiet; and friction against any part of the stethoscope, either from the patient's or practitioner's dress, or otherwise, must be carefully guarded against during auscultation.

It is not proposed here to enter into a full explanation of the several methods of investigating thoracic maladies, which would occupy entirely too much space, but to briefly refer to several points connected with them, as simple guides to the practitioner. There are so many excellent monographs upon these methods of diagnosing, which should have a place in every medical library, that it would be superfluous to enter into minute details.

INSPECTION requires the chest to be exposed so that its form, size, and movements may be observed. It should be practiced anteriorly, laterally, and posteriorly, and these several conditions of one side of the chest must be closely compared with those of the opposite side. The practitioner will stand at a short distance from the patient, and first take a front view of each region, and then a view in profile. Among females it is better not to expose the upper part of the body all at once, but only those parts in front, at the sides, and back, as we wish to inspect them. Healthy chests are generally of regular form, having both sides symmetrical, and their respiratory movements equal. Deformity of the chest, it must be borne in mind, may arise from other causes than disease of the lungs or pleura, and care should be taken to discriminate between such malformations and those originating from disease.

If there be a *depression or contraction of one portion of the chest*, it may be due to disease of the lung beneath, causing diminished power of expansion, and obliging the chest-wall to sink down upon it, as in tuberculous excavations; or, it may originate from compression of the lung from some cause external to itself—most probably in the pleura—the depressing cause having disappeared, and the chest-wall being allowed to apply itself to the diminished lung, as, after empyema. The depression will appear the greater from the sound lung becoming larger, owing to its having to perform double work.

If there be an *enlargement of one portion of the chest*, it may be due to increased function of the inclosed lung, compensatory to loss of function at some other part; to diseased increase in the size of the inclosed lung, as, in emphysema; or, to an accumulation of some abnormal matter in the chest, as in the case of intra-thoracic tumor, empyema, hydrothorax, or pneumothorax. When this

matter is in the pleural sac, its specific gravity will influence its position.

The *size* of the chest, and any variations in size between the two sides, can not be accurately judged of by the eye; it is more satisfactorily determined by mensuration. Generally, right-handed persons have the right side of the chest somewhat larger than the left, and vice versa.

The *movements* of the walls of the thorax during respiration may, in disease, be augmented or diminished in frequency. In health, the *thoracic* movements predominate in the female, the *abdominal* in the male. If, therefore, the respiratory movements in a male should have the character of those normal to a woman, they would in him indicate disease, and be called "thoracic respiration." If, on the other hand, the breathing movements of a woman should have the character of those normal to a man, they would in her indicate disease, and be called "abdominal respiration." In both sexes the movement of *forced inspiration* predominates in the thoracic portion, and while the chest-wall is elevated, the abdomen actually recedes. This may be particularly observed when the respiration is rendered forced and laboring by disease.

In health, the average number of regular respirations, or expansions among adults, is from 15 to 20 per minute; and, during each respiration, the heart beats about four times. As a general rule, when a pulmonary disease is attended by increased respiratory movements, there is not a corresponding excess in the heart-strokes.

"When disease exists in the chest, if the *thoracic breathing movements are in excess*, the disease is one either interfering with the action of the diaphragm, as in peritonitis, tympanitis, abdominal tumors, or ascites; or in which the difficulty of getting air into the lungs, is so great, that all the muscles of the chest-wall are exerted, to attempt—by elevating it and taking off the pressure from the lungs—to induce the further expansion of these organs and the consequent ingress of air, as, in some cases of bronchitis, (capillary), spasmodic asthma, laryngitis, and the like.

If the *abdominal breathing movements are in excess*, the disease is one requiring the diaphragm, to compensate, by excess of action, for deficient action in the muscles of the chest,—for loss of the healthy resiliency of the lungs,—or for both; as in pleurodynia, some cerebral diseases, etc.

If the *breathing movements are one-sided*, it may be due to deficiency on one side, or to excess on the other, or to both,—the excess compensating for deficiency; and these affections may be in the chest-

wall, as, in intercostal neuralgia, in the pleura (*pleurodynia*), or in the lung.

If the movement of expansion is deficient but elevation remains, the loss of power is in the lung, but it may be due to disease of its own structure, as, in phthisis, or, to pressure from without, as, in consolidation from the pressure of interpleural fluid.

If the expiratory movement is undue in length, the disease is one offering an impediment to the escape of tidal air from the lungs which may be due to actual obstruction in the tubes, or to loss of power on the part of the lung to contract upon the air and expel it. Thus, it occurs in bronchitis, in tubercle, and to its greatest extent in emphysema.

If the respiratory movements are excessive in rapidity, it may be due to any disease preventing the full expansion of the lungs at each inspiration, whence an attempt is made to compensate the loss of quantity by increased rate; or to imperfectly aerated blood, or to any disease increasing the rapidity of the circulation, whence an attempt is made to supply air to the blood at a rate proportionate to the demand.

If both thoracic and abdominal breathing movements are deficient, it is due to a combination of diseases interfering with the action of the diaphragm and the external muscles of the chest, or to paralysis, or, most probably, to general exhaustion, in which case the deficient action will be broken at intervals by a sighing inspiration, as sufficient power accumulates for the effort."

PALPATION is an application of the hand to the exterior surface of the chest, to detect,—any painful or tender spots on touching certain parts; the frequency of breathing; the absence or presence of certain vibratory motions of the thoracic walls, or the degree to which these vibrations are influenced by disease, or to which their transmission is increased or diminished by interposing media; the comparative temperature of different parts of the surface; the presence of fluid indicated by fluctuation, etc. Palpation may be effected in two ways:—1. When the symptoms of the disease are limited to a small extent, by pressure with the tips of the fingers, as in the ordinary exercise of the sense of touch; and, 2, by placing the palms of the hands upon both sides of the chest, gently and evenly and with such a moderate degree of pressure as to enable them to participate in—but not to deaden—the vibrations, or to appreciate the excess or defect of movement in the two sides, and thus to compare the results.

Standing behind the patient, the physician will place his thumbs, one on the top of each scapula, resting his fingers, firm and flat, on the collar-bones and upper ribs; then directing the patient to sigh deeply, the examiner, looking along his fingers is enabled to compare the motion of the two *upper lobes* of the lungs with one another. If a bright light shines on the finger nails, a difference in expansion of one-twentieth of an inch, can be detected, when present.—If the ends of the thumbs are then placed on the lowest dorsal vertebra, and the hands be extended so as to span the waist as far as possible, requesting the patient to again sigh, the extent of motion of the *lower lobes* can be felt.

Palpation—below the clavicles in the female, and below the epigastrium in the male—is the best mode of learning the number and force of the respirations.

The vibrations experienced by the hand in palpation, are the following:

Vocal vibration or *fremitus*, or the vibrations of the lung, produced by the voice, and transmitted through the chest-wall. When the palm of the hand is lightly applied upon the chest of a healthy person, a slight thrilling sensation (*vocal fremitus*) will be communicated to the fingers. This is more marked in adults than in children, in males than in females, in short-chested than long-chested persons, and in the spare and thin than in the fat and stout; it is also most distinct over the larynx and trachea, also appreciable over the upper parts of the chest, but becoming gradually extinct as we advance downward. It may likewise be produced in the act of coughing, and its intensity is considerably modified by the voice, being more appreciable in cases where the voice is low, deep, and powerful, than where it is sharp and feeble. It may also be detected by the ear, and is more strongly marked when the person is lying down. The natural vocal fremitus or thrill is generally better appreciated on the right side than the left, and it may be increased or diminished by disease. It is abnormally *increased* where lung substance consolidated by interstitial deposits comes closely in contact with the chest-wall. When the lung has its density thus increased, its conducting power is increased, and, unless the increase be very great, the fremitus is more or less augmented, as, in congestion of the lung, the early stages of pneumonia, in tubercular infiltration, and in œdema of the lung. It is abnormally *diminished* or *annulled* when the lung becomes solid, or when fluid collects in the pleural sac, as, in the stage of pneumonic hepatization, and in pleuritic effusion. Thus, in both lung consolidation, and pleuritic effusion, there is dullness on percus-

sion, and resistance to the percussing finger, but vocal fremitus is only increased in the former.

Sometimes, a vibration is produced by the bronchial valves or rhonchi, which is termed the *rhonchal fremitus*; and, at an advanced stage of pleurisy, when the effused fluid is absorbed, and the roughened surfaces of the pleura are brought into contact, a distinct cracking sensation or rubbing movement (pulmonary *friction fremitus*) is conveyed to the hands, and is very distinct at the same time, on auscultating. When the lungs or pleuræ contain fluid, a sense of *fluctuation* may be detected in the intercostal spaces, with a diminished or annulled vibratile tremor. (See *Heart's Impulse*, page 339; *Fremissement Cataire*, page 344; and, *Cardiac Friction Fremitus (Exocardial Friction Murmurs)* page 342.)

By MENSURATION any deviation of the chest from the state of health may be detected; and this must always form a part in minute examinations, as, thereby, can be ascertained more exactly the comparative bulk and volume of the two sides of the chest, as well as the amount of expansion and retraction of the chest-walls during inspiration and expiration. But for clinical purposes, inspection affords sufficiently exact information, as a general rule. The simplest method of measuring the circumference of parts, or the distance between any two fixed points, is by means of a graduated tape, taking care to apply the tape at the end of an ordinary expiration, while the patient holds his breath. The fixed points usually selected in measuring, are, the spinous processes of the vertebræ posteriorly, and a line drawn through the center of the sternum and umbilicus, anteriorly; and, in measuring from these to other points, the tape should be carried evenly between the points, and on an exact level. As a general rule, the right side of the chest measures about half an inch more than the left; in left-handed persons, it will be the left side that is largest, or both sides may be equal.

Enlargement of one side of the chest may be occasioned by pleurisy with effusion, pneumothorax, hydrothorax, hypertrophy of the lung, emphysema, and cancerous tumors of the lung or pleura. Contraction of a side may be due to, pleurisy at the period of absorption with retraction, pleuro-pneumonia, tubercular deposit in the second stage, chronic consolidation of the lung, and infiltrated cancer of the lung.

The diameter of the trunk, in various directions, is best ascertained by means of a pair of callipers.—Various instruments have

been invented for practising mensuration, as Quain's stethometer, Sibson's chest-measnrer, Alison's stetho-goniometer, and Hutchinson's spirometer. For analytical investigations these instruments may be useful and necessary, but for clinical purposes, inspection and palpation will generally be sufficient; in some cases, however, we may more accurately determine the amount of expansive movement by Quain's instrument. The spirometer only measures the volume of air expired by the lungs, or the vital capacity of these organs, and the information it furnishes as to the existence of disease is of a negative character.—Mensuration may be made more especially useful, by measuring the chest from time to time during the treatment of disease of the thoracic organs, in order to determine the changes for better or worse in the size, etc., of the chest-walls, as they gradually progress.

SUCCUSSION is rarely necessary. It is performed by gently but abruptly pushing the chest of the patient backward and forward, while the observer's ear is applied to the chest; or, the patient may make the movements himself. The sound developed by this, resembles that of water in a partly-filled decanter held close to the ear, and shaken; the precise tone, however, will vary with the density of the fluid, and the proportion of fluid and air present. This sound, termed *splashing*, is elicited in cases of pneumo-hydrothorax, involving, in most cases, a fistulous communication between the lung and pleura, but not necessarily. It may sometimes be heard in phthisis, where there is a large tuberculous cavity partly filled with fluid. This thoracic splashing is sometimes accompanied with a ringing sound, or with metallic tinkling.

PERCUSSION is one of the most important means of physical diagnosis in diseases of the chest. It consists in striking the chest in such a manner as to elicit sound, and is of two kinds—*immediate*, or *direct*, when nothing intervenes between the percussing agent and the part percussed; and *mediate*, when some solid substance—as the finger or a disk of ivory—is placed upon the chest, so as to receive the blows made when percussing. This intervening medium is termed a *pleximeter*. Mediate percussion is the one usually pursued at the present day. One, two, three, or four fingers of the left hand, pressed firmly against the chest, serving as the pleximeter, while the ends of the fingers of the right hand, brought together in a line, form the *percussor*. Or, an ivory disk, held between the

thumb and index finger of the left hand, by two movable handles attached to the disk, forms the pleximeter; while a small steel hammer attached to a stiff spring handle, and having a piece of caoutchouc inserted in its percussing surface, forms the percussor. Both of these plans are used, the first, with the fingers, is usually preferred in private practice in examining chest diseases.

In practicing percussion it is best to strike first on one side of the chest, and then on the corresponding spot of the other side, in order to compare the character of the sounds; as it is not the sound elicited which determines the presence or amount of disease, but the relative degree of the dullness or resonance observed on each side. The strokes given should be made at right angles to the part percussed, and should be made quickly, smartly, and uniformly; and if the fingers be used as the percussor the movement of striking should be made from the wrist alone, in the same manner as the keys of a piano are struck by a well-trained pianist, the fore-arm and arm being held motionless. The pleximeter should always be held firmly against the chest, and the firmer it is held, and the more forcibly the blow struck, the more readily do we develop the sound of deep-seated organs; but, on no account, should the blow be too forcible, there is a limit to it. The examiner must not go on hammering long at a time, but should compare, by two or three quick strokes, each place with the corresponding place on the other side.

The parts should be percussed in the following order: 1, on right clavicle; 2, on left clavicle; 3, under right clavicle; 4, under left clavicle; 5, above right scapula; 6, above left scapula; 7, close under right scapula; 8, close under left scapula; 9, under right mamma, (an inch below); 10, under left mamma; 11, right lateral region; 12, left lateral region; 13, upper middle and lower sternal regions. In order to become a good diagnostician, the medical man should percuss and auscultate the chests of healthy persons, whenever he has the opportunity, for the first thing to start with in these examinations, is, a perfect acquaintance with the healthy sounds developed by these methods. By such investigations he will ascertain that, even in health, pulmonary resonance will vary in different persons in quality, pitch, duration, and degree of intensity, according to the size of the lungs, the elasticity of the chest-walls, the quantity of muscular and adipose tissues, etc. He will also ascertain that corresponding portions of the chest, as a general rule, yield, on each side, identical sounds. Indeed it will be found highly advantageous to practice percussion upon bodies of all kinds, until the ear is perfectly familiar with the differences of each, and can identify them with the eyes shut.

The sounds elicited by percussion of the chest are as follows,—and if we are acquainted with the normal sounds of the several parts percussed, we become enabled to judge whether the following sounds are indicative of a normal or abnormal condition of the parts from which they are obtained, more especially when taken in connection with all the other symptoms present:

1. *Clear*, also termed *pulmonary*, or *vesicular resonance*, and which is due to the presence of air. The lungs yield their normal, full, clear sound, slightly more and more distinctly from above downward, owing to their increasing capacity; the sound being muffled, however, by the pectoral muscles, the mammæ, and the scapulæ. On the right side, from the sixth rib, a dead sound is produced from the presence of the liver; the same is elicited on the left, from the junction of the fourth costal cartilage with the left border of the sternum, to the point where the heart's impulse is felt, owing to the position of the heart; while below on this side, to the left, at the sixth rib, the sound will be tympanitic, owing to the empty stomach being subjacent. At the ninth or tenth rib, well-marked dullness, and a feeling of resistance to the finger, are observed, and which are due to the presence of the spleen. The clear or hollow sound is always produced when the chest is struck over a portion of healthy lung; but a distinct difference in the sound may be observed when elicited immediately after a full inspiration, and a full expiration. This difference is never detected when the tissue becomes indurated from any cause.—The subsequent remaining percussion sounds, are morbid, and indicate abnormal conditions; they are—

2. *Increase of clearness*, or *exaggerated vesicular resonance* of low pitch, long duration, and diminution of its vesicular quality, is due to an abnormal increase in the quantity of air in the lung-cells, and is observed in vesicular emphysema. When the vesicular quality of the resonance is substituted by one of a tympanitic character, the increase of clearness being of a higher pitch and short, this may then be due to pneumothorax, etc.—Increase of clearness and a duration of sound, with diminished elasticity, is observed where there is a surplus of air in the subjacent part, with considerable induration of tissue between the surface and the part containing that surplus,—a combination of conditions sometimes met with in phthisis, when a superficial cavity in the lung has a thin, indurated, and adherent external wall.

3. *Diminution of clearness*, or *diminished vesicular resonance*, also termed *dullness*, may vary from a slight degree to perfect dullness, in proportion to the increased density,—with shortening in the duration of the sound, and is due to solidification of the lung, or

to compression. The degree of diminution of the normal vesicular resonance is due to the amount of air in the lung-vesicles, or to the displacement of air by an augmentation of the solid matters contained in the chest. Diminution of vesicular resonance is met with in most pulmonary diseases. Slight pleuritic effusion, congestion and partial condensation of the lungs, and during the paroxysm of spasmodic asthma, are the chief causes of a partially dull sound on percussion. In hydrothorax, the dullness of resonance will be observed above the level of the fluid. In pleurisy with great effusion, in hydrothorax, in pulmonary apoplexy, in complete condensation of the lung from pneumonia, in phthisis, in cancer of the lung or pleura, in hypertrophy with cardiac dilatation, in pericarditis with effusion, and over aneurismal tumors, there will be a greater or less diminution of normal resonance, in proportion to the amount of air in the air-cells, and the quantity of air displaced by an increase in the solid parts.

A tympanitic resonance with increase of clearness is sometimes present above the level of the fluid, in many instances of pleuritic effusion; this may also be observed in the healthy lobe of the lung, the lower lobe of the same side being solidified, as in pneumonia; there may also be a tympanitic sound from deposits at the apex of the chest; and also in the lower lobes, the sound being transmitted from the stomach and intestines. These form exceptions to the general rule given in the preceding paragraph.

A complete *absence of resonance* is termed a *flat* sound, like that produced when the thigh is percussed. This flatness may be due to the presence of effused fluid in the pleural sac, and is obtained only below the level of the fluid; to complete solidification of the lung in pneumonia (the lower lobe); and to tumors.

By marking the point of the upper margin of the flatness, and then, after causing the patient to change from the vertical to the horizontal posture, by again percussing, if there be fluid in the pleural sac, the flatness will be found to have also changed its position, in consequence of the fluid having moved with the patient's change of position. In the first instance, the level of the fluid will be nearly at right angles with the median line of the body; in the second, it will be nearly parallel with this line. With flatness there will almost always exist an increased resistance, the ribs being less flexible than usual under external pressure.

4. *Tympanitic resonance*, or drum-like sound, requires that the cavity from which it is elicited by percussion shall be full of air, but shall not communicate freely with external air; it is best produced by percussion over the empty stomach, or over a portion of

intestine filled with air, but is never obtained on percussing the healthy chest. With the exception of flatness or absence of sound, all abnormal resonances which are not vesicular, are termed "tympanitic." A purely tympanitic sound has no vesicular resonance whatever; though it may vary in clearness, loudness, and other qualities,—thus we may have "tympanitic clearness," "tympanitic dullness," etc. The tympanitic sound may generally be distinguished from the clear or pulmonary resonance, by its higher pitch, its more ringing character, and its being non-vesicular. When it occurs, we may infer that a cavity filled with air exists beneath the spot percussed; and, consequently, in thoracic affections we obtain the clearest tympanitic sound in pneumothorax. But the tympanitic sound may be quite dull or of less intensity when the thoracic walls are rendered extremely tense, from the great distension occasioned by the large accumulation of air in the chest. It may also be produced less perfectly in two conditions of the lung, independently of pneumothorax, viz.:—1. In the emphysematous portions of lung which often surround lung-tissue solidified from hepatization, tubercles, etc.—in emphysema, the sound usually retains a portion of vesicular resonance. 2. When the lung is gradually recovering from the compression of fluid previously effused into the pleural sac.—Tympanitic resonance, and its several modifications, subsequently referred to, are present in a comparatively small number of cases in which cavities exist in the lungs; to elicit them, the cavity must be large, seated near the exterior of the lung, and have rather firm parietes to prevent collapse. They are more frequently observed in tuberculous excavations.

5. *Amphoric resonance* is a modification of the tympanitic tone—it requires that the cavity percussed shall communicate freely with external air. The sound has a metallic, tinkling character, and is similar to that produced by striking an empty, or partially empty wine cask, or, by snapping the finger upon the tense cheek with the mouth somewhat open, in order to produce a sound resembling that of pouring fluid from a bottle. Amphoric resonance is indicative of a large cavity, in which the air can vibrate, and is more generally heard in cases of large tuberculous cavities, more or less empty, and having firm and elastic walls. It is occasionally heard in pneumothorax. When a small amount of fluid is contained in the cavity, metallic tinkling (*gutta cadens*) will frequently be heard, owing to drops of the fluid falling from the upper part of the cavity into the liquid below.

6. *Tubular resonance* is another variety of the tympanitic sound;

it is elicited from an elastic tube filled with air, and is natural only when produced over the larynx or trachea. In dilatation of the bronchi, in chronic consolidation of the lung, and in some cases of pleuritic effusion, it may be heard over the bronchi. Occasionally, it may be heard in pneumonia, in small tubercular cavities, and in cancer around the bronchial tubes.

7. The *Bruit de pot fêlé*, or cracked metal sound, may be very closely imitated by taking a vulcanized rubber ball with a small aperture in one side, and while it is placed upon a table, lay one finger upon it as a pleximeter, and then percuss the ball, the air from which puffs out at the hole; if a small glass or metal tube is pushed into the hole so as to project a little into the cavity of the ball, the sound of air in escaping acquires a more metallic quality. It may also be produced when the closed hands are struck upon the knee to imitate the sound of coin in the hands. To elicit this sound, the patient must open his mouth while his chest is percussed, so that no impediment may exist to the sudden exit of air through the respiratory tubes; the percussing blow must give the impulse slowly and heavily, and allow the fingers to press forcibly on the part for some moments after it has been given. It is indicative of a cavity, having thin, elastic walls, communicating freely with a bronchial tube. If the walls of the cavity are simply hard and leathery, however elastic, no metallic timbre is given to the sound, but rather a hissing noise; if they are more dense and vibratile, the air, impinging on the borders of the aperture by which the cavity communicates with a bronchus, may produce a sound more of a cracked-pot character. The sound is caused by the sudden, forcible ejection of air along the bronchial tubes communicating with the cavity; but it has been elicited at the top of the chest among healthy children.

AUSCULTATION is an investigation of internal diseases by the sense of hearing, or by listening to the sounds produced beneath the part auscultated; mankind are deeply indebted to the genius and energy of Laennec for this invaluable diagnostic method. There are two modes of auscultation; the one termed *immediate*, where the ear is placed in contact with the surface of the part to be auscultated; the other, *mediate*, by means of the stethoscope, or some other conductor of sound, placed between the surface of the patient's body and the ear of the auscultator. For most purposes, immediate auscultation will be found the best; mediate auscultation is preferred with fastidious, as well as uncleanly persons, where the surface is une-

qual, where it is desirable to limit the sounds in order to more correctly analyze them, and where the ear can not be well placed against the parts, as, in the axilla, around the clavicle, etc. Sometimes, both methods will be required during an examination. A common hollow cedar-wood stethoscope, with the trumpet-shaped end not too much, expanded, is the best. One equally as good, but somewhat more troublesome to use, is, a stethoscope with a flexible tube, which admits of application to various parts without requiring much change of position, or uncomfortable position, of either patient or physician. The double flexible stethoscope of Dr. Cammann, has the disadvantage of intensifying, and in a measure confusing sounds, as well as changing or modifying their quality and pitch; but when the physician has once educated his ear to its peculiarities, he will find it an excellent and very valuable instrument, having an advantage over the others in several respects, as, by rendering obscure morbid sounds more distinctly heard, by more thoroughly eliciting the differences of intensity, the rhythm, etc.

As a general rule, auscultation is best performed with the patient in a sitting posture, having him assume the same positions, when the several regions are auscultated, as named for percussion in these regions. Occasionally, the enfeebled condition of a patient may require him to be examined in bed, while in the recumbent position; this may answer very well for the anterior regions, but will be found quite troublesome for the lateral and posterior, to auscultate which, it will be desirable to raise the patient to a sitting posture, and have him properly supported, whenever his condition will permit this. The following rules should be attended to:

1. The patient, as well as the physician, should be placed in an easy position, one admitting of ready auscultation, without stooping, straining, or holding the head too low, and without giving rise to fatigue or constraint. If the patient be seated low, or be lying down, the physician will find it best and more convenient to rest on one or both knees. A flexible stethoscope is best suited to these examinations in the recumbent position.

2. Immediate auscultation may be practised with a thin towel or piece of muslin over the chest; but in mediate auscultation, the chest should be naked, though, with the female, only such parts should be exposed at a time as are undergoing examination. The room should be kept comfortably warm.

3. The stethoscope should be placed closely against the surface, without an undue degree of pressure; it may be held between the thumb and index finger, or, if it be a double stethoscope, the patient may hold it. And great care should be observed not to rub the

instrument with the fingers, nor to allow anything, as, clothing, etc., to come in contact with it externally, as the least movement or contact will interfere with the examination by giving rise to extraneous sounds. The room should be kept perfectly quiet, as outside noises draw off attention and confuse the sounds. Whenever it can be done, the stethoscope should be held in its place solely by pressure with the ear; but when required to be held otherwise, the fingers should be placed upon it only directly above its trumpet extremity.

4. Any agitation on the part of the patient increases the action of the heart, and disturbs breathing; consequently, in such cases, the examination should be postponed until the patient becomes more calm, and free from excitement.

5. Corresponding points on each side of the chest should be examined in connection, one after the other, in order to correctly form a comparison between them; examining the same points several times, if there is any doubt. And the auscultation should be made during breathing, during forced respiration, while coughing, while whispering, and while the patient is counting from one to five, repeating each number with the same degree of strength and intonation. Auscultation should also be made in order to discern the sounds produced by percussion.

But no physician can successfully auscultate, who is not well versed in the normal sounds of the voice and of respiration,—in the healthy laryngeal, tracheal, bronchial, lung, and heart sounds. He should auscultate the old and young, strong and feeble, thin and stout, males and females, of his acquaintance, as frequently as possible; and so educate the ear as to be perfectly certain that a respiratory murmur is healthy; that is, that it comes from a vesicular lung-substance in its healthiest state, and is conducted to the chest-wall through structures in their healthiest state. The center of the clavicle in front, or rather a little below the center, is the point at which the examination is to be commenced, then on the corresponding point at the other side, and so proceed alternately from one side to the other, at corresponding points, with each region of the chest, until its whole surface has been explored. In all cases where auscultation is practised, the intensity of any sound, its character or quality, its position, its pitch, its duration, and its rhythm, should all be taken into consideration, as modifications of these properties possess diagnostic importance.

1. The normal sound caused by the ingress and egress of air to and from the lungs, during inspiration and expiration is termed the *Pulmonary, Respiratory, or Vesicular murmur*. It is of a gentle, soft,

silken, breezy character, is more distinct during inspiration, though almost continuous like one prolonged sound, and is heard all over the chest in health, except at those points where it is superseded by a bronchial or laryngeal respiration. However, it is not exactly identical in every part of the lungs, and is better marked at the point below the center of the clavicle. It is louder during childhood, on which account the term *puerile*, has been applied to an increased respiratory murmur; it is also louder in females than in males. Its quality and pitch will be found to vary in different persons, though not to an extent that will destroy its diagnostic value. The vesicular quality of this sound is more distinctly marked during inspiration, that of the expiration being somewhat of a blowing or tubular quality.—Healthy vesicular murmur cannot be imitated by anything, but must always come from healthy lung; but it must not be forgotten that, as it obscures the sounds which pass beneath it in the healthy bronchi, so may the sounds of disease be going on beneath it, and yet be inaudible; and also that, in its turn, vesicular murmur may exist, but not be heard. The principal changes to be observed in normal respiration, that are indicative of disease, are the following:

a. *Prolonged expiratory murmur* may be observed; it is indicative of an impediment to the escape of breathing air, and may be due to increased density of the lung-substance, by which its resiliency is impaired, as, in tubercle; to a distended condition of the air-cells, preventing the normal collapse of the lung during expiration, as, in emphysema; or, to a diminished calibre and elasticity of the tubes through which the air has to escape, as, in bronchitis. When present, it may be observed by listening to the patient's chest when he is asleep, or is not attending to the examination, at which times he will generally draw a sharp, short breath, and then expire as long as he can. When the impediment to the exit of air from the vesicular structure of the lungs is very great, a necessity for muscular effort will arise, and then the expiratory movements will be *prolonged and labored*, as, in chronic bronchitis.

b. *Exaggerated, puerile, or supplementary respiration*, are the terms applied to an increased or unnaturally loud respiratory murmur. This increased sound is indicative, either of temporary excitement, or of the presence of disease in some part of the lungs. Thus, when one lung is rendered powerless, from the compression of fluid effused in an inflamed pleura, or, when a portion only of a lung becomes solidified, as, in pneumonic hepatization, the intensity of the respiratory murmur will be increased in the healthy lung, or in the unaffected parts of the diseased lung, owing to the

necessarily increased functional activity of the same, the compensating powers of the healthy lung-texture being brought into play.

c. Weak, feeble, or deficient respiration, are terms applied to a diminished or suppressed respiratory murmur; it is present when air is prevented from freely entering the lungs, and is commonly more marked during inspiration than during expiration. Great caution is needed in concluding that the respiratory murmur is abnormally deficient, unless the change is well marked, as it may be masked by pleuritic effusion. When it occurs on the right side it is a more valuable sign than when on the left. The difficulties to the free entrance of air into the lungs, which occasion weak vesicular murmur, are, general debility, paralysis, pain from pleurisy or pleurodynia; foreign bodies in the trachea or bronchi; diseases of the larynx, or trachea; bronchitis; thickening or compression of the bronchial mucous-lining membrane; partial infiltration of the lung with tubercle; compression of the lung-tissue by pleuritic effusion, or morbid growths; and old age.—*Suppression or absence* of the respiratory murmur may be due to complete obstruction of a bronchus; pleurisy with abundant effusion, and flatness on percussion at the lower part of the lung; pulmonary apoplexy; during a severe paroxysm of asthma; and, occasionally, in infiltration of the lung with tubercle or other morbid matters, and associated with flatness at the upper part of the lung.

d. Jerking, interrupted, wavy, saccadée, respiration, are terms applied to the respiratory murmur when it does not occur in one soft, continuous strain, but is divided into one or more parts; it is associated with inspiration, which is affected, as it were, by several disconnected efforts. This modification may occur from so many different causes, and may likewise be absent though either of those causes exist, that it is not one to which much diagnostic value can be safely attached. If, however, the interrupted inspiration is confined to the apex of one lung, and it is clear that pleuritic adhesion does not exist there, the sound acquires some value as a sign of increased density of that portion of lung, from tubercular deposits.

e. Rough, harsh, or rude respiration, are terms applied to a murmur, which lacks the peculiar softness of the vesicular murmur, and consists of a combination of the vesicular and bronchial sounds, and hence more correctly termed by some writers, *broncho-vesicular respiration*. The inspiration is harsh, tubular, and of high pitch, while the expiration, if present, is apt to be prolonged, of

higher pitch than inspiration, and of a blowing character. This is another of those delicate changes in the quality of the respiratory sound which may or may not be valuable as a sign of early disease, according to co-existing circumstances. And the signs at an early period of disease are so few, so subtle, and so unsatisfactory, yet the information sought from them—the detection of altered structure, almost before it is altered, while disease pauses on the threshold—so eminently important, that it behooves us especially to weigh the meaning of any language in which it is told, however faint the tones. Rough respiration may be said to grow out of prolonged expiratory murmur, and to grow into bronchial breathing. It is heard in incipient tuberculization, dry bronchitis, vesicular emphysema, chronic pulmonary consolidation, dilatation of the bronchi, and incipient cancerous infiltration of the lung, in cases where the lungs are slightly compressed by plastic or tuberculous matter in the pleura, in the resolution stage of pneumonia, at different periods of pleurisy, and in pulmonary apoplexy. By itself, rough respiration, indicates only that the vesicular structure is, from some cause or other, impeded in its equable, resilient expansion and contraction; other signs or circumstances must be co-existent to give specific value to this change of sound as diagnostic of any particular form of disease. A normal increased loudness of the breathing sounds are often observed on the right side when compared with those on the left, and must not be mistaken for a rough respiration. Rough respiration is considered a valuable sign in the early period of tubercular consumption; yet, as Skoda observes, solitary tubercles, however abundant, do not necessarily interfere with the vesicular respiration.

2. *Bronchial respiration* appears to be a mixed sound, being tubular, blowing, harsher than the vesicular sound, but often associated with it, and of somewhat higher pitch. It may be heard over the large bronchial tubes, that is, at the upper part of the sternum, between the scapulæ on a level with their spines, or with the second and third dorsal vertebræ, and less clearly under the clavicles and in the axillæ. Bronchial respiration exists throughout the whole bronchial tree, and needs only a change in the conducting medium to bring it audibly to the surface; it always indicates disease when heard elsewhere than at the two points where they exist in the healthy chest, as, condensation of the lung from infusion into its air-cells and parenchyma, which occurs in the second stage of pneumonia, in pulmonary œdema, pulmonary apoplexy, malignant or tubercular deposits, intra-thoracic tumors, etc. The sound is loud in proportion to the extent and degree of condensation, and

the proximity of the condensed portion to the larger bronchi, and is entirely free from any vesicular murmur.

a. Cavernous respiration is considered to be a modification of the bronchial; it is a blowing or tubular sound of low pitch, non-vesicular, of a circumscribed extent or proportioned to the size of the cavity occasioning it, and is not present if the cavity is occupied with fluid—on which account it is often intermittent in its character, being present when the cavity is empty or partially so, and absent when it is entirely filled with liquid. Inspiration takes place slowly, with a pitch lower than the healthy sounds; expiration, when present, is of still lower pitch. Cavernous respiration when heard in situations where vesicular respiration alone exists in health, is indicative of a cavity with firm, smooth, but yielding walls, not too soft to reflect sound, not collapsing during breathing, and which communicates with the bronchial tubes. Other cavernous signs may be associated with it, as, gurgling, metallic tinkling, and pectoriloquy, which will be referred to presently.

If auscultation be properly performed, there is no part of the chest-wall, after passing the first sternal bone, from which cavernous sounds can be detected in a state of health; yet, in listening above the clavicles, we must be careful not to carelessly direct the stethoscope toward the trachea, instead of in a line with the perpendicular axis of the chest, as tracheal sounds may be heard, and be mistaken for cavernous.—Although the sounds of bronchial tubes may become audible at the surface of the chest, through increased conducting power of the structures interposed; these tubes are not large enough in health to give sounds like those from the trachea, except perhaps at their bifurcation.—Cavernous sounds are produced under conditions which almost insure their reaching the thoracic parietes, viz.: 1. A cavity so large that the vibrations of a considerable volume of air may be transmitted to its walls; 2. These walls must present a large surface from which vibrations may be conducted to the ear; 3. The walls must be of a certain density, which implies, almost of necessity, increased density of the surrounding structures—that is, increased power of conducting sound; 4. A cavity so large and so defined, that it will, almost necessarily, communicate freely with some of the bronchial passages upon which it has intruded, thus acquiring free ingress and egress of air during respiration, speaking or coughing.

Hence when the sounds, which in health are audible only on auscultating the trachea, are heard at any part of the chest except over the trachea and its bifurcation, it positively indicates the existence, not only of a cavity, but of one larger than is consistent with

health. Nevertheless, cavities, the result of disease and large enough to be of serious consequence, may exist without producing any cavernous sounds. Therefore, although these sounds are positive evidence of the existence of a cavity, their absence is not positive evidence that no cavity exists; they thus lose much of their value; for it is just in those cases in which they are not audible, that it is most important to detect the existence of disease—cases in which the general symptoms are not very marked, and which are not too far advanced to afford a reasonable prospect of recovery.

b. Amphoric respiration is another modification of the bronchial; it is a blowing sound, somewhat like that produced by blowing into an empty decanter, with the mouth at a little distance from the neck. It may be of low pitch and humming, or ringing and metallic, and has an echo from the parietes of the cavity. It is diagnostic of a large excavation, and is more apt to be heard in pneumo-hydrothorax with a fistulous communication between the cavity and bronchi. It may be absent or present, the same as with cavernous respiration, and the remarks made under this head, relative to its diagnostic value, may be applied to the present sound. *Metallic tinkling*, and *gutta cadens*, which may be also associated with amphoric respiration, the voice, or cough, will be referred to hereafter.

3. *Laryngeal and tracheal respiration* or *murmurs*, are heard over the larynx and trachea, the sounds are more intense, drier, and hollower, than the bronchial; the sound during expiration is more prolonged, and of higher pitch than that during inspiration, and the expiratory and inspiratory sounds instead of being continuous, are separated by a short interval. These sounds are termed “tubular,” because they resemble the noise made by a current of air forced through a tube of large size. They may be exaggerated or feeble. In health there is no cavity in the lung large enough to yield them, after the first bone of the sternum has been passed; therefore, whenever heard elsewhere than over the larynx or trachea they always indicate disease, having the same indications as the cavernous respiration and its modifications.

ABNORMAL OR ADVENTITIOUS SOUNDS are termed *rales*, *rattles*, or *rhonchi*. They differ from the preceding in never being heard during health, and in not being modifications of the normal respiratory sounds. They are occasioned by air passing through the air-tubes when these are contracted, or when they contain liquid;

the first are termed *dry* or *vibrating rales*, the second, *moist*, *mucous*, or *bubbling*.

The dry sounds are divided into *sibilant* and *rhonchus*. Take a piece of vulcanized rubber tubing, three feet long and two lines in the bore; with this a number of useful lessons may be learned. Rest about half the tube on the table or against the wall and lightly apply a stethoscope upon it; listen, while with one end of the tube in the mouth, you inspire and expire through it alternately. The sounds heard will be something like loud bronchial breathing. Make pressure upon one portion of the tube so as to diminish its calibre at that part, and, if it is perfectly dry, *sibilant* sounds will be produced when the tube is most compressed, and sonorous snoring *rhonchus* when the calibre is only slightly diminished. By varying the extent and degree of compression, changes in the character and pitch of the breathing sounds may be produced, as numerous as those heard in the chest. It is most interesting to observe the effect of moisture in the tube, and how minute a quantity affects its sounds. If sixty drops of water are put into the three-foot tube, and the auscultation and breathing repeated as before, *large crepitation*, most abundant and loud, will appear to fill the tube for a considerable part of its length. If pressure is now made, as for the production of *rhonchus* and *sibilus*, the size of the crepitation will diminish as the calibre of the tube is decreased. If we empty the tube and blow through it to expel all the moisture possible, and again auscultate, crepitation will be heard, not of the same character as before, but more crackling, yet still distinctly bubbling; and if the tube is compressed the sounds become smaller, and assume nearly the character which they had before the water was emptied out. At parts where the tube appears dryer, loud *rhonchus* is heard, less musical and more harsh than from the dry, compressed tube. So slight an amount of moisture is sufficient to give the crepitation and *rhonchus*, that it is most difficult, having once moistened the tube, to get it again so dry as not to produce these sounds; so that we can not help wondering how it is that the human air-tubes are ever free from *rhonchi* and crepitations when lubricated by even their normal amount of secretion.

1. *Sibilus*, or *sibilant rale*, is a high-pitched, hissing, wheezing, or whistling sound, produced in the small bronchial tubes and vesicles, and is indicative of acute catarrh or bronchitis; it augurs some danger.

2. *Rhonchus*, *snoring*, or *sonorous rale*, has a low or grave pitch, resembles a droning hum, like the cooing of a pigeon or the bass note of a violin, is produced in the larger bronchial branches, is of

less dangerous import than sibilus, and indicates catarrh or bronchitis seated in these large tubes. It may exist alone, or be associated with sibilus. Each of these sounds may vary as to intensity, tone, location, appearance and disappearance, occurring with expiration, or inspiration, or both, etc.

These are the most common of all the morbid sounds detected by auscultation; are frequently heard without any other sign of disease, and generally occur at some period of its course, in company with every disease of the lungs. They may be heard in many varieties by listening to a sleeping child with a "cold in the head." As the nasal passages alter in the amount of obstruction they present to the tidal air, by their tumid walls or by their secretions, at one moment rhonchus is heard, at the next sibilus, and again, perhaps, normal respiration; or either sound may be persistent until the child sneezes and clears the passages, or opens its mouth, and ceases to use the nose for respiration.

As already remarked, rhonchus and sibilus are produced by any causes, temporary or persistent, by which the larger air-tubes are diminished in calibre over a limited extent—so that air passing through a tube of a certain diameter is suddenly met by some obstruction, that obstruction not being sufficient to entirely block up the passage; if the obstacle is of such a character that it will vibrate freely as the air rushes past, the snoring, cooing, or more sonorous noises, classed as rhonchus, are produced; if the obstacle is such as to considerably diminish the calibre of the tube for some distance, the more hissing and less sonorous varieties of sound, called sibilus are produced. Hence sibilus, although it may have its origin in the larger tubes, is most frequent when the smaller, more terminal, bronchial passages are affected—when their lining membrane is tumid, and their calibre thereby diminished; while rhonchus is more frequently produced in the larger tubes when they are partially obstructed by swelling of the lining membrane, by pressure from without, or by portions of adhesive secretion hanging to their walls and vibrating as the tidal air passes by. Rhonchus is, therefore, under ordinary circumstances a less persistent sound than sibilus, being more easily removed by forced respiration, or by cough.

3. *Crepitant rale*, or *rhonchus*, also termed *fine crepitation*, is a dry sound, although usually classed among the moist. It is a peculiar and delicate sound, one of the most valuable revealed by auscultation, and may be imitated by rubbing between the thumb and finger a lock of one's own hair, close to the ears; or, according to Dr. E. A. Carr, of Canandaigua, New York, by moistening the thumb and finger with a drop or two of paste, or mucilage of gum arabic,

and then holding them to the ear while alternately separating them and pinching them together. There is no bubbling sound associated with it, as it is of a crackling character, is almost always limited to the inspiratory act, and once established, it is persistent, not being removable by coughing or by expectoration, but remains until replaced, either by some other morbid sound, or by the happy return of normal respiratory murmur. It must be most scrupulously distinguished from the small crepitation of capillary bronchitis, with which it is too apt to be confounded, and which is bubbling, accompanies both expiration and inspiration, and may be removed for a time by cough and expectoration. Fine crepitation is heard in its true character only in the first stage of pneumonia. In the lobar form of pneumonia it generally exists during the whole course of the disease. It is generally limited to one side (unless both lungs are affected with pneumonia), and may be best heard below the scapula: while small crepitation is heard on both sides. Both fine and small crepitation may be heard when pneumonia is complicated with capillary bronchitis. Fine crepitation is also an indication of phthisis, when detected at the superior anterior part of the chest, and limited to a narrow area.

4. *Mucous rales*, or moist bubbling sounds, are heard when any kind of fluid, as, pus, blood, etc., exists in the bronchi; they vary in character according to the calibre of the tubes in which they are seated, may be irregularly present, may shift their location from one part to another, and are termed, according to their degree of tone, coarse and fine, the first being heard in the larger bronchi, the latter in the finer ramifications. They result from the passage of air through a liquid, and are directly occasioned by the formation and bursting, in quick succession, of numerous little air-bubbles.

The *coarse* or *large bubbling sounds*, also termed *large crepitation*, occur in the larger air-tubes, in which the air-bubbles are large, and indicate the presence of fluid in these tubes, as, in pulmonary catarrh, bronchitis with secretion of mucous, hemoptysis, abscess, oedema, the last stage of tuberculous disease, etc.

5. The *sub-crepitant rale*, also termed *small crepitation*, is another moist rale, which is produced in the smaller ramifications of the bronchi, and differs from the preceding rale in being much finer. It is a sign of much value in diagnosis.

When we hear a number of very small bursting bubbles or "crepitations," accompany an expiratory act, it tells us that air is issuing from the fine passages or cells of the lungs in a number of minute streams, and that these encounter some fluid before they

have united into a blast of larger size; and as the air must be introduced through the same tubes before it can be expelled, the crepitation of inspiration needs no further explanation; hence, "small crepitation," speaks unmistakably of fluid in the remote ramifications of respiratory tubes. If, on the other hand, the crepitations are of larger size, they tell that they must have larger spaces to contain them, and that the stream of air which produced them had a certain calibre. This is the interpretation of crepitation of various sizes, rising from the exceedingly delicate bubbling, almost like effervescence, of capillary bronchitis, to large, noisy crepitation, and thence even to "gurgling." Once understanding the acoustic conditions of crepitation, it will be evident that it is not necessary for the air or fluid to be confined in the respiratory tubes:—that a portion of lung-substance, broken down in structure and converted into a soft semi-fluid mass, if freely communicating with previous respiratory tubes, may have the air from these passages forced through it, and thus yield crepitation similar to that from fluid in the tubes themselves. Thus, crepitation may be yielded by masses of tuberculous deposit lying in the course of the air passages, and reduced with the involved lung-substance to a fluid condition; again, crepitation may be due to inflammatory exudation into the air-passages themselves. Crepitation then, both large and small, indicates the presence of fluid, and the passage of air through it, but for its special pathological meaning in any given case, we must look to the signs and circumstances which bear it company,—as, those of pulmonary apoplexy, œdema, etc.

6. *Gurgling*, also termed *cavernous rale*, and *humid crackle*, may be produced in the largest bronchial tubes, but it then retains more of the characters of large crepitation, and has not those peculiar characteristics which gurgling acquires in cavities of larger size—and which convey to the mind a definite impression of a considerable volume of air passing through a mass of fluid, and of that fluid becoming greatly agitated, or leaping up into an atmosphere in which the sounds it produces are reflected from the surrounding walls. As a sign of the existence of a large cavity containing both air and fluid, this description of gurgling takes rank, with metallic tinkling and amphoric sound, as a sign of a large cavity containing air. When audible, all these phenomena are of the greatest importance. But a cavity may exist, and gurgling be absent. If the gurgling be distinctly heard at the summit of either lung, it is in all probability indicative of a cavity from

tuberculous softening. This sound should be carefully discriminated from the coarse mucous rales.

7. *Friction or attrition sound*, is generally difficult of detection by the ear alone, but if the hand be placed upon the affected part, a sensation of rubbing is generally perceived, which is then communicated to the ear by auscultation; it attends both movements of respiration, but is loudest and most prolonged during inspiration. It occurs in pleurisy, when, the polish of the healthy serous membranes being lost by the exudation of lymph, the rubbing of the costal upon the pulmonary pleura is distinguished. It of course ceases when the exudation of serum is sufficient in quantity to separate the costal from the pulmonary pleura, but returns as the fluid poured out becomes absorbed, continuing until the lymph itself is also absorbed, or, until the opposed surfaces of the pleura become adherent. The individual characters of pleural friction sounds may vary—with the degree to which the opposing surfaces are roughened, with the consistence of the exudation, and with the extent to which the respiratory movements are restricted by pain. Thus, in the first stage of dry, tumid, vascularity, if any sound is produced, its character is usually rather soft and grazing; in the second stage, ridges of adhesive, sero-plastic exudation may give a grating or sawing sound; and in chronic pleurisy, when the interpleural matter has become variously altered in consistence, and more or less adhesion has occurred between different portions, the friction sound may acquire creaking, rumbling, and other modifications.

In examining cases of chronic pleurisy, or of the acute disease in persons who have suffered from a previous attack, it is necessary to remember that adhesions may have been effected between the pulmonary and costal pleuræ, which, by restricting movement, may interfere with the production of friction sounds; and when the pleural cavity is becoming distended with liquid effusion, the lung, in other parts pushed back from the chest-wall, may, at the points of adhesion, be held in contact with the ribs, and thus complicate the diagnosis.—Friction sound may also occur when deposits of tubercles or carcinoma are so localized as to cause roughening of the pleura, or even when interlobular emphysema gives rise to the same conditions.

AUSCULTATION OF THE VOICE is almost always had recourse to by physicians while examining the condition of the lungs; and, as with the other auscultatory signs, these are of but small value in the diagnosis, except when taken in connection with

the various other symptoms present. The *vocal fremitus* or vibrations which occur during speaking, in a healthy chest, have already been referred to under Palpation; these vibrations may be heard as well as felt; and are more distinct among deep-toned adults. The vocal sounds undergo several changes during disease, which have been termed as follows :

1. *Bronchophony* or *increased vocal resonance*, is the normal vocal sound heard more or less distinctly over portions of the lung where it is not heard in health. The sound is dull, distant, feebly vibratory, resembling a distant, confused, humming noise. It is indicative of condensation of the lung in the vicinity of large bronchial tubes, the result of pressure or deposits, and is more generally present in pneumonia, and in phthisis with tubercular deposits, though it is of more value in the former than in the latter disease, owing to its being more constantly present. It may also be present in several other diseases that give rise to increased density of the pulmonary tissue. Bronchial respiration and bronchophony are frequently heard together; but since the sound of the voice is much louder than the sound of respiration, bronchophony may often be heard before the lung has become sufficiently solid to render bronchial respiration audible.

2. *Diminished* or *suppressed vocal resonance*, over the parts where the resonance should exist in health, is present in many cases of emphysema, and solidification of lung-tissue, in cases of obstruction of one of the large bronchi, in pleurisy, in pneumothorax, hydrothorax, etc. It is an inferior sign.

3. *Pectoriloquy*, a modification of bronchophony, is where the voice passes into the ear, as if it came from and through the stethoscope; it is natural over the trachea, but when heard elsewhere is indicative of disease. It is generally caused by solidification of lung-tissue around a dry cavity having free communication with the trachea through the larger bronchi, and has been termed *cavernous* and *amphoric voice*. It may also arise from a very solid state of lung alone, or from consolidation of the lung around a dilated bronchus. However, it is often impossible to distinguish a dilated bronchus containing fluid from a tuberculous cavity. When a metallic sound (*amphoric*) is also present, we may almost always safely diagnose a cavity. Nothing can be determined from pectoriloquy, except it be taken in conjunction with all the other signs.

4. *Ægophony*, is another modification of bronchophony, it consists of a peculiar tremulous resonance of the voice, resembling the

bleating of a goat, or the voice of Punch, following, or accompanying the words of the patient. It is usually heard at the inferior and posterior portion of the chest, near the larger bronchi. It is changing, being very faint or quite strong, with more or less tremulousness, is not always constant, may be of variable duration, and may be heard at any portion of the chest. It is indicative of a small amount of fluid in the pleural cavity, and may be met with in pleurisy and hydrothorax. It has also been heard in simple consolidation of the lung, when no fluid could be detected in the pleural sac; but, in most cases, it appears to be due to pleuritic effusion; when the effusion is large, it disappears.

AUSCULTATION OF COUGH is frequently practised, and is subject to the same rules as are applied to that of the voice. The principal sounds are termed, 1, *Bronchial* or *tubular cough*, which is heard over the chest, the sound being similar to that heard over the trachea in health, upon coughing. It indicates the same conditions as bronchial respiration, and bronchophony.

2. *Cavernous cough* is of more limited extent than bronchial, is more or less intense, blowing, prolonged, and imparts a heaving shock to the auscultator's head, as if raising it from the chest or stethoscope. Its indications are the same as those of cavernous respiration.

METALLIC TINKLING is a peculiar sound, which is frequently met with in auscultation, whether of the respiration, voice, or cough, and is of great value in the diagnosis of disease when present. On applying the stethoscope over some portion of the chest-wall and making the patient speak, abnormal vocal resonance of cavernous character is heard, and almost at the same time a tinkling or ringing sound, as of a half-muffled bell. The same occurs if the patient coughs, and, sometimes, also during respiration. If a glass bell is suspended in air, and then a small blast of wind be suddenly directed against its margin, we may hear, first, the rush of air, and then following it at a distant interval, a faint ring of the bell; the same effect is produced if the gust is directed against the interior wall of the bell. This corresponds in essential characters with the sound called metallic tinkling. In the human chest, this sound is due to the presence of a cavity of considerable size, with dense vibratile walls, containing air; and a blast of air impinging upon some portion of its walls, usually either upon the edge of an opening into the cavity, or upon the inner surface of its parietes, occasions the sound. It is heard in pneumothorax, and tuberculous excavation; more generally in the former, when there is a

fistulous communication between the lung and the pleural cavity, and of which disease it is considered almost pathognomonic.

If the walls of such a cavity are *damped* in their vibrations, or are too thick, or not sufficiently dense, or if a blast of air into the cavity is not forcible enough, metallic tinkling may not be excited in its walls, and reflection alone, or combined with imperfect metallic resonance, may take place, and produce a sound of the peculiar character known as *amphoric echo*. (See *Amphoric Respiration*, page 530.)

A drop of fluid falling from a height on to the surface of a fluid, in a space bounded by reflecting or vibratile walls, containing air, produces a peculiar and characteristic sound to which the name *gutta cadens* may be appropriately applied. If we suspend lightly a thin glass or metal flask, so that it can ring when struck; and, while listening attentively, with the ear close to, but not touching the wall, pour some water slowly, drop by drop into it from the neck, a dropping is heard accompanied by a slight ringing sound, but quite distinct from the sound in the experiment named for metallic tinkling. This dropping corresponds in essential characters with the *gutta cadens* sound. As the water collects in the flask the dropping becomes more dead, is raised in pitch, and the ring of the flask is lost.—This sound is produced by the falling of drops of exudation from the walls of the pleural sac in pneumothorax, into the fluid of empyema or of hydrothorax, or of drops of pus from the roof a large tuberculous cavity into the liquid secretion on its floor.

The acoustic conditions present, may be intermediate between those necessary to the true metallic tinkling and those essential to amphoric echo—producing sounds of intermediate character; while the conditions necessary to *gutta cadens* include those of both the other sounds; and hence, not improbably, has arisen that confusion between *gutta cadens*, metallic tinkling, and amphoric echo, and the theories of their production, so commonly met with among teachers of auscultation.

Isolated signs are of no value in the detection of disease; it is only when all the signs are associated together that we are enabled to arrive at any correct and satisfactory diagnosis. And in the several diseases to which the thoracic organs are liable, there are usually a multiplicity of signs which depend upon the same physical conditions and tend to corroborate each other. Thus, certain symptoms associated in a group, indicate most clearly the existence of consolidations, liquefactions, or excavations, etc., as will be

observed in the groups of physical signs given in the Note below,* which I extract from H. Dobell's "Demonstrations of Diseases in

CONSOLIDATIONS.*

1. ISOLATED (MILIARY) INTERSTITIAL TUBERCULOUS GRANULATIONS.

Deposited outside the air-cells.

Inspection, Palpation, Mensuration, give no constant results but the infraclavicular regions are usually flattened.—*Percussion* normal; or slightly impaired if some tubercles are very superficial; or increased resonance from superficial emphysema.—*Auscultation* unsatisfactory. Respiratory sounds may be harsh; expiratory murmur usually prolonged; inspiratory murmur may be jerking; or vesicular murmur may be absent or nearly so; or co-existent bronchitis may produce rhonchus, sibilus, or crepitation of varying size.—*Vocal resonance* gives no constant results.—*Cough* may be present, or not.—*Sputa* none, or colorless, frothy, watery, or mucilaginous looking. Hemoptysis may be present or not in varying quantities.

2. CONGLOMERATED INTERSTITIAL TUBERCULOUS GRANULATIONS, the same as No. 1, deposited in groups; involved vessels, bronchial terminations, and air-cells obliterated by pressure. In parts—traversed by large previous bronchi.

Expansion diminished, chest-wall may be flattened. Vocal fremitus plus.—*Percussion* dull; resistance increased.—*Auscultation*, see No. 1, minus—respiratory murmur, if the deposit is abundant; plus—bronchial breathing and voice, where traversed by large previous bronchi; and conducted heart sounds.—*Cough* almost essential, rarely paroxysmal.—*Sputa*, see No. 1, plus—sometimes a grumous deposit from the thinner sputum, resembling that from barley-water; glairy mucous with streaks of yellowish or buff opaque matter, becoming less and less aerated.

3. INFILTRATED TUBERCLE. Deposited inside the air-cells and passages.

In some places collected into groups, in others scattered.

See No. 2, strongly marked; plus—*Sputa*, more or less mixed with tuberculous matter.

4. APOPLEXY OF THE LUNG, AFTER COAGULATION. Effusion of blood, with laceration, into the interstitial areolar tissue; without laceration, into the air-cells and passages.

No Signs from small masses, unless quite superficial. From large masses or groups of small masses, resistance plus.—*Percussion* impaired or dull.—*Auscultation*, respiratory murmur diminished or absent;—in the neighboring parts harsh. Where the coagula are traversed by permeable bronchi, bronchial breathing and cough, vocal fremitus plus.—*Cough* varies in character with the primary disease.—*Sputa* hemoptie, generally darkish in color, rarely a large quantity of blood, but tinged mucous striæ of blood, pure blood. See Nos. 17, 18.

5. HEALED CAVITIES. Fibro-cellular cicatrices and chalky concretions.

Chest-wall depressed.—*Percussion* dull.—*Auscultation*, vesicular murmur absent. If previous bronchi are involved, bronchial breathing and voice.—*Cough*, variable.—*Sputa*, more or less, as Nos. 1, 2, 3, plus—occasional particles, of different sizes, of cretaceous matter.

the Chest," etc., to which valuable work I am indebted for much of the matter in the preceding subject of auscultation. By a

6. FIRST STAGE OF PNEUMONIA. ("ENGORGEMENT.")

Costal movement restricted, if pleuritic pain. Vocal fremitus normal.—*Percussion* impaired in proportion to the amount of engorgement. *Auscultation*, respiratory murmur weak, or suppressed in the affected parts, exaggerated in the neighborhood and in the opposite lung. Vocal resonance somewhat increased when exudation has commenced. *Fine crepitation* on deep inspiration, especially after cough, persistent after expectoration. It may be masked by the rhonchus, sibilus, or large crepitation of bronchitis, but with care may generally be caught at the end of a deep sighing inspiration.—*Cough* moderate, rarely paroxysmal.—*Sputa* sanguinolent or rusty, viscid, semi-transparent, adhesive, slightly aerated. The tint may vary,—occasionally liquorice, or prune-juice color, or watery, brown, or blackish,—in rare cases only white and viscid,—more rarely absent. N. B. ACUTE EDEMA OF THE LUNG presents the physical signs of No. 6, except that the crepitation is less *fine*. *Sputa not* sanguinolent, but watery or muco-purulent.

7. SECOND STAGE OF PNEUMONIA. ("RED HEPATIZATION"), *traversed by pervious bronchi.*

Signs of No. 2, marked; minus—flattening of the chest-wall; plus—blowing or tubular quality of respiration. In the circumference of the affected part, signs of No. 6 may often be heard.—*Cough* and *Sputa*, see No. 6. The sputa may gradually become simply muco-purulent.

8. SECOND STAGE OF PNEUMONIA, *passing into the third.*

Signs of No. 7, passing into those of No. 15.

9. MEDULLARY CANCER.—10. HARD CANCER.—11. MELANOID CANCER.

Signs of Nos. 2, 4, and of No. 12, according to the extent and situation of the disease; plus—noticeable *flattening* of the chest-wall in infiltrated cancer; *protrusion* in actual thoracic tumor. The disease is usually limited to one lung. Dullness on percussion sometimes extending over the mesial line.—*Cough* invariable, very rarely dry.—*Sputa* catarrhal, purulent, often intimately mixed with blood, giving a red or black currant-jelly appearance, cancerous matter rarely mixed; free hemoptysis frequent; fetor of the breath occasional.

12. INDURATED LUNG, THE EFFECT OF PNEUMONIA, *traversed by permeable bronchi.*

Signs of No. 7. Dullness and resistance especially marked.—*Cough* and *Sputa* not characteristic.

LIQUEFACTIONS.

13. SECOND STAGE OF BRONCHITIS, *exudation into the bronchi of fluid, at first viscid and frothy, afterward more opaque and muco-purulent.*

Rhonchal fremitus occasionally felt. *Percussion* usually normal, but resonance may be slightly increased or slightly impaired.—*Auscultation*, vesicular murmur

careful study of these groups, an immense amount of valuable information of a practical character will be obtained, and which, if

impaired. Inspiration and expiration accompanied by crepitation of various sizes, also rhonchus and sibilus. (*In capillary bronchitis the crepitation is so small that care is needed not to mistake it for true "fine crepitation."*)—*Cough* loose, may be loud and hoarse, occasionally paroxysmal.—*Sputa* white, frothy, adhesive, becoming ropy, faint yellow, or greenish, or gray, usually running together; sometimes in pellets and opaque.

14. CHRONIC BRONCHITIS. *Thickened, vascular, bronchial mucous lining, exudation of muco-serous and muco-purulent fluid.*

Expiratory movements prolonged and labored, antero-posterior expansion plus superiorly. *Percussion* often slightly impaired over the lower lobes, unless emphysema co-exists.—*Auscultation*, every variety of cooing, whistling, snoring, rhonchus—mingled with large crepitation and occasional clicking and ticking sounds. Vocal resonance may be increased.—*Cough* frequently suffocating and paroxysmal, varies in severity.—*Sputa* usually copious, of nauseous odor, in large masses little or not at all aerated; yellowish, greenish, ash-colored, or grayish green—occasionally streaked with blood; sometimes scanty and adhesive, and sometimes (bronchorrhea) copious watery, glairy fluid follows each paroxysm of cough.

15. THIRD STAGE OF PNEUMONIA. *Purulent infiltration replacing the plastic lymph of the Second Stage, No. 7.*

For Signs see No. 7 (Second Stage of Pneumonia), plus—crepitation of different sizes when the suppurating tissue communicates with bronchial tubes.

16. SECOND STAGE OF TUBERCULOUS DISEASE. *Reduction of the tuberculous matter and involved lung-tissues to the consistence of pus.*

For Signs see Nos. 1, 2, plus—increased depression of the chest-wall, and crepitation of various sizes, at first very small. *Cough* essential, troublesome, often provoking vomiting. *Sputa*, see No. 3, plus—purulent, non-aerated pellets, and often abundant muco-purulent matter mixed with bronchial mucus.

17. APOPLECTIC COAGULA IN THE LUNG, SOFTENING.

For Signs see No. 18, plus—bronchial breathing and voice from the yet unsoftened portions, if they involve permeable bronchi.—*Cough* not characteristic.—*Sputa* sooty or bistre-colored blood, mixed with mucus, or muco-purulent matter.

18. APOPLEXY OF THE LUNG BEFORE COAGULATION, *with and without laceration of tissue. Effusion of blood into the air-cells and passages, also into the interstitial areolar tissue.*

a. Small Exudations, may present no signs, or crepitation only. *b. Large Exudations*, vocal fremitus increased if permeable bronchi are involved.—*Percussion* impaired or dull, according to the amount and superficialness of the effusion.—*Auscultation*, crepitation of all sizes.—*Cough* varies with the primary disease.—*Sputa*, tinged mucus, or finely aerated florid blood mixed with mucus. Sometimes profuse discharge of florid blood, more or less aerated.

aided by ability to percuss, auscultate, etc., correctly, and by a proper understanding of the phenomena thereby produced or

EVACUATIONS.

19. A LARGE EMPTY TUBERCULOUS CAVITY, *with smooth reflecting walls, and free bronchial communication. The surrounding lung consolidated with tubercle.*

Chest-wall depressed; expansion diminished. Vocal fremitus marked.—*Percussion* dull.—*Auscultation*, respiration, voice, and cough, cavernous. If the walls of the cavity are very dense and thin, the lung immediately encompassing them not consolidated, there may be *metallic tinkling*, or *amphoric echo*, on sudden, forcible inspiration, cough, or voice.—*Cough* varies, generally hollow.—*Sputa*, none from the cavity, but from surrounding lung may be of various characters.

20. A CAVITY SIMILAR TO No. 19, BUT CONTAINING SECRETION.

For Signs see No. 19, plus—gurgling and large crepitation, the vibration of which may sometimes be felt on the chest-wall.—*Cough* troublesome, only relieved by expectoration.—*Sputa*, pellets with sharp irregular outlines, or larger masses with flocculent edges, of yellowish color; or broad, flat, non-aerated lumps, smooth, greenish, remaining distinct; or ash-colored pure pus not remaining distinct, sometimes discharged suddenly and profusely. Any of these may be mixed with blood.

21. A VERY SUPERFICIAL TUBERCULOUS CAVITY FULL OF AIR, *free bronchial communication, the thin stratum of super-imposed lung consolidated.*

The chest-wall occasionally bulges over the cavity. Vocal fremitus marked.—*Percussion* clear and tympanitic, may be metallic, and if the bronchial communication is large and free it may be amphoric. *Bruit de pot fêlé* may sometimes be produced if the cavernous wall is elastic.—*Auscultation*, if no secretion, No. 19, marked: if secretion, No. 20, marked.

22. SMALL TUBERCULOUS CAVITIES, *bronchial communication very imperfect, super-imposed stratum of lung normal, surrounding bronchi inflamed, containing secretion.*

Chest expansion may be normal. Vocal fremitus normal.—*Gentle Percussion*, normal.—*Strong Percussion* may yield more or less fullness.—*Auscultation*, bronchial respiration absent, or imperfect, or occasional large crepitation, rhonchus, and sibilus from surrounding bronchi.—*Cough* dependent principally on the bronchitis.—*Sputa* differ with the amount of bronchial communication with the cavity, etc.

23. A VERY LARGE TUBERCULOUS CAVITY, *with a thick stratum of densely consolidated lung super-imposed, free bronchial communication.*

Percussion weakly tympanitic, if forcible, quite dull if gentle.—*Auscultation*, respiration, voice, and cough, cavernous. If the cavity contain secretion, gurgling.

24. EMPHYSEMA. *Enlarged air-cells, with attenuated anemic walls; in some places the contiguous cells have coalesced*

Chest-wall elastic, more or less rounded, especially in front and superiorly. Vo-

detected, will enable any physician to correctly diagnose the greater part of lung affections.

cal fremitus variable.—*Percussion* morbidly clear, sometimes tympanitic, unaltered by respiration.—*Auscultation*, expiratory sound peculiarly long and labored; but it may be weak, inaudible, or masked by rhonchus and sibilus. Inspiratory sound weak and short, or it may be inaudible or masked.—In extensive emphysema, the heart sounds are displaced and the area of pulmonary resonance extends beyond its normal limits.—Dyspnoea constant, subject to paroxysmal aggravations.—*Cough* not constant, but usual, paroxysmal, and suffocative.—*Sputa* frothy, liquid, mucous; often accompanied with the sputa of bronchitis. Nos. 13, 14.

25. BRONCHIECTASIS. *Bronchi dilated, cylindrical, flask-shaped, sacculated, etc., containing secretion. Surrounding lung condensed by pressure, in the immediate neighborhood of the tubes.*

For Signs see those of Tuberculous cavities of different sizes and positions. Moist sounds abound, and rhonchus and sibilus are generally associated.—*Cough* essential, generally very troublesome and paroxysmal.—*Sputa* No. 20, copious and opaque, odor usually nauseous; also No. 14. There is seldom much blood.

26. A GANGRENOUS CAVITY.

Percussion dull.—*Auscultation*, gurgling and large crepitation, the vibrations of which may sometimes be felt on the chest-wall.—*Cough* variable.—*Sputa* horribly fetid, dirty greenish, brownish, or ash gray, very liquid, mixed with portions of disintegrated lung-tissue.

27. PNEUMONIC ABSCESS. *The purulent contents more or less excavated—remains of hepatization in the surrounding lung.*

For Signs see Nos. 20, 23, according to the position and size of the cavity, minus—metallic sounds. If evacuation of the contents is prevented by absence of bronchial communication, see Signs of No. 7.—*Cough* varies.—*Sputa* purulent, or muco-purulent, sometimes contain degenerated lung-tissue; may be fetid.

PLEURISY, ETC.

28. NORMAL LUNG, *with increased function.*

Costal movements increased in expansion and elevation.—*Percussion*, undue resonance during inspiration.—*Auscultation*, respiratory murmur increased in the intensity and duration of both sounds, the expiratory slightly in excess; an increase unattended with modification of any kind, either in respect of quality, softness, or liquidness, (The increased proportion of the expiratory sound is very slight.) Vocal resonance *slightly* increased in intensity.

29. FIRST STAGE OF ACUTE BRONCHITIS. *The bronchial mucous membrane vascular, dry, tumid,—diminishing the calibre of the tubes unequally.*

Percussion normal.—*Auscultation*, respiratory murmur impaired in fullness, clearness, and softness, becoming harsh,—especially the respiratory sound, which is

DISEASES OF THE NASAL ORGANS.

OZÆNA.

OZÆNA or Rhinorrhea is a greater or less discharge from one or both nostrils, of a puriform or sanious character, and of an exceed-

prolonged. Rhonchus and sibilus constant or occasional.—*Cough* essential, frequent, dry,—may be hoarse, loud, ringing, paroxysmal.—*Sputa*, none, or white, adhesive, *finely* frothed mucus in small quantity.

30. FIRST STAGE OF PLEURITIS. *Pleura vascular, rough, and dry. Subpleural cellular tissue injected and tumid.*

Costal movements restricted by pain.—*Percussion* scarcely or not at all impaired.—*Auscultation*, respiratory murmur weak, superficial, jerking. *No friction sound yet* (except in some cases unattended with pain.)—*Cough* usual, but not essential; dry, short, small, suppressed.—*Sputa* none, or a little viscid mucus.

31. SECOND STAGE OF PLEURITIS. *Slight sero-plastic exudation on the pleural surfaces.*

Vocal fremitus usually normal. If impaired it is in proportion to the amount of exudation. The vibration of pleural friction *may* be perceptible to palpation. *Percussion* impaired in proportion to the amount of exudation. *Auscultation*, *pleural friction sound* accompanies expiration, inspiration, or both. Respiratory murmur weak, jerking, distant, or inaudible.—*Cough* and *Sputa* see No. 30.

32. THIRD STAGE OF PLEURITIS. *Considerable sero-plastic exudation, separating the costal from the pulmonary pleura, compressing the lung, depressing the diaphragm, and displacing organs.*

Intercostal depressions obliterated, costal movements lost. Vocal fremitus lost.—*Percussion* perfectly dull, with increased resistance.—*Auscultation*, *no friction sound*. Respiratory sounds lost. Vocal resonance may be bronchophonic or lost. A peculiar tremulous bronchial voice, sometimes heard from the line of commencing dullness to a line at which all voice sounds are lost. *Ægophony* occasionally—especially in a line with the inferior angle of the scapula. (Heart sounds may be conducted.) Increased circumference of the affected side, most marked round the false ribs.—*Cough* and *Sputa*, see No. 30.—N. B. HYDROTHORAX. *An effusion into the pleural sac of serum, free from the products of inflammation.*—For Signs see above, No. 32. It is usually double.

33. PNEUMOTHORAX. *An abnormal collection of atmospheric air or gas in the cavity of the pleura, compressing the lung and displacing organs.*

Increased convexity of the affected side. Intercostal depressions obliterated. Elastic resistance increased. Vocal fremitus impaired or lost.—*Percussion* purely tympanitic—often extending beyond the middle line. If the left side is affected, *heart dullness* is obscured or lost.—*Auscultation*, respiratory sounds weakened by distance, or lost, according to the volume of the air or gas; but between the

ingly offensive odor; it is a symptom only of disease in some part of the nasal cavity. I have met with several cases, however, of a most fetid, repulsive character, in which there was no appreciable discharge.

Ozœna is *caused* by, or is rather symptomatic of, chronic inflammation of or ulceration of the lining mucous membrane in the deep recesses of the nose, and generally accompanied with a discharge; or, it may be due to periostitis, ending in suppuration, caries, and necrosis, in a strumous person, or, from syphilitic disease of the parts. Cancerous affections in the vicinity of the parts may also give rise to it. The disease may also proceed from decomposition of retained mucosities in the nasal cavity without any ulceration; from a deformity, whether congenital or acquired, but which prevents the free discharge of the mucosities of the nose; and, in some cases, from a morbid condition of the economy at large, inducing modification in the condition of the nasal secretion,—just as we meet with intolerable stinking secretion from the feet in persons perfectly clean,—a peculiar odor from the axilla, occurring in others besides the red-haired, in whom it is normal,—and an insupportable condition of the breath in certain menstruating women,—and in which cases, no signs of inflammation or ulceration can be detected by the most careful examination. The offensive odor which characterizes ozœna, does not necessarily come from the inflamed or ulcerated parts, but generally from a retention of mucus, or mucopurulent matters, and their consequent putrefaction.

“The most common origin of ozœna is neglected catarrhal

scapulæ an obscure bronchial murmur may usually be found. Frequently in perforative cases, amphoric or metallic character of cough, voice, and respiration—heard especially in the neighborhood of the perforation of the lung, whether this is patent or not.—*Cough* and *Sputa* of the concurrent disease of the lung.

34. THE WHOLE LUNG COMPRESSED.

At the upper part several EMPHYSEMATOUS CELLS, ruptured on the lung surface, allow the escape of air into the pleural cavity. *At the middle part*, TUBERCULOUS CAVITIES, ruptured on the lung surface, and communicating with bronchi, allow the escape of air into the pleural cavity, and permit purulent matter to drop into the fluid empyema beneath. *At the lowest part* the LUNG IS SIMPLY COMPRESSED.

35. EMPYEMA WITH PNEUMOTHORAX. *Air and fluid at once in the cavity of the pleura.*

For Signs see Nos. 32, 33,—plus—succussion-sound when the chest is shaken; and perhaps *gutta cadens* from drops of exudation falling on the surface of the empyemic fluid,—heard usually after coughing or change of posture.

inflammation, in patients of scrofulous habit; and when once established, the bones may participate in the diseased condition. There is a peculiar appearance of the nose, a thickening, and quasi-romanizing of the nasal bones, so that the upper part of the organ looks broad and prominent, while the lower part has a sort of pinched or twisted appearance, which characterizes the early victims of ozæna. Moreover, there is that terrible aspect of scrofula, which Cullen describes, the swelled columna and alæ nasi, and the swinish pouting of the upper lip, which are realized to the full only in case of scrofulous ozæna." (*R. Druitt.*)

The *symptoms*, in addition to the fetid smell, which is frequently so repulsive as to keep the best of friends at a distance from the patient, vary somewhat, according to the character and location of the disease. When limited to the nostrils or parts in their immediate vicinity, uneasy sensations are experienced, an increased stuffing up of the nose, a fetid yellowish discharge, and at times a greater or less quantity of crusts, clot, or fleshy matter is passed, frequently a dull aching is complained of, and occasionally acute pain, especially just previous to the accumulation of the matters named above, and in some instances there will be more or less epistaxis. If the frontal sinus is affected, in addition to some of the preceding symptoms, there will be a constant and more or less severe headache across the affected sinus. In either instance there may be a nauseous taste in the mouth, and frequently, the sense of smell is lost, or impaired. As already remarked, instances will sometimes be met with in which the only symptom that can be observed, is, the fetor. The disease usually progresses slowly, without producing acute pain, unless it be of cancerous origin.—The *rhinoscope* should always be used, which will enable us to discover, in very many instances, the seat, extent, and nature of the local difficulty. Tumefaction, and deep-red, velvety appearance of the turbinated bones may be seen, sometimes extending to the ethmoidal and superior turbinated bones,—the result, sometimes, of general periostitis; or, there may exist ulcers of the nasal fossæ, of the turbinated bones, granulations on the floor of the nostril, etc.

The *prognosis* of ozæna, as far as relates to the offensive odor is, as a general rule, favorable; but as regards the disease upon which this depends, the prognosis must be governed by its character, as to a scrofulous, syphilitic, or cancerous, etc., origin, and by the nature and extent of the local inflammation or ulceration.

The *treatment* of ozæna is constitutional and local. The constitutional measures will depend upon the conditions present; if the

patient be anemic, preparations of Iron, Manganese, etc., as named under Anemia, will be indicated; if there be a general weakness of the system, without anemia, vegetable tonics may be used, as Elixir of Cinchona and Iron; Decoction of Cinchona a fluidounce and a half, Dilute Nitric Acid ten minims; mix; the whole to be taken in a day, in three doses of half a fluidounce each,—the same to be repeated every day; Compound Wine of Comfrey, etc. And if there be a scrofulous, syphilitic, or scorbutic taint present, the appropriate remedies for such malady should be prescribed.—The diet should be nutritious; moderate exercise be taken daily in the open air; and the digestive organs should be kept in as healthy a condition as possible,—any derangement of which is apt to increase the difficulty. A proper attention should likewise be paid to the skin and kidneys.

. The local measures consist in cleansing the nasal cavities from accumulations of putrid and other effete substances; and in applying weak medicinal solutions to the affected parts, by injections or otherwise. In many instances, frequent injections of tepid water, by removing extraneous matters, will effectually remove all offensive smell; other instances will require some disinfecting fluid, as, a very dilute Solution of Carbolic Acid; of Labarraque's Solution; of Pyroligneous Acid; of Chloride of Zinc; of Chlorate of Potassa, ninety grains to one pint of Water and one fluidrachm and a half of Hydrochloric Acid, to which, in some cases, a very small amount of Tincture of Myrrh may be added; of Iodine two grains to Glycerin one fluidounce; of decoction of Rhatany Root six fluidounces in which Chloride of Lime half a drachm has been well rubbed—let it stand an hour, strain, and inject half an ounce at a time, repeating it three or four times a day; or of Permanganate of Potassa, two to ten grains to a pint of Water, etc. Some of these agents, in addition to their disinfecting influence, will also exert a very beneficial therapeutical action upon the affected parts. Dr. T. G. Comstock, of St. Louis, Missouri, who has had considerable experience in the treatment of ozæna, informs me that he has been very successful with a Decoction of Logwood, used internally, and also as an injection into the nasal cavity; he considers it almost a specific for this affection.—These injections are usually effected by means of a large syringe made expressly for this purpose; but, they frequently fail in reaching the deeper-seated cavities, and hence are of but little account when these parts are affected.

Recently, a discovery has been made by Prof. Weber, of Halle, for a knowledge of which I am indebted to Dr. J. L. W. Thudicum, of London,—and which enables one to reach the deepest recesses

of the nasal cavity by fluid injections. I will give a description of it as nearly as possible in Dr. Thudicum's language.—When one side of the nasal cavity is entirely filled through one nostril with fluid by hydrostatic pressure, while the patient is breathing *through the mouth*, the soft palate completely closes the choanæ, and does not permit any fluid to pass into the pharynx; while the fluid easily passes into the other cavity, mostly round and over the posterior edge of the septum narium, in some persons also through the frontal sinuses, and escapes from the other open nostril, after having touched every part of the first half of the cavity of the nose, and a great part, certainly the lower and median canal, of the second half. By means of the application of this principle to the treatment of diseases of the nose, it is possible easily and frequently to wash the nasal cavity, to disinfect and deodorize it, to remove the sordes which accumulate so easily in it, and to apply to its surface a great number of beneficial medicinal substances, so as to prevent acute affections from extending, and to incline them toward a speedy recovery; to stop hemorrhages, allay irritations and subdue in a remarkable manner chronic affections of the Schneiderian membrane, so as to re-establish a perfectly healthy surface and normal condition of the organ of smell.

The *apparatus* for this purpose consists of a stout rod of iron, about thirty inches in length, and fastened upright into a heavily loaded foot, or, it may be screwed upon a table. Upon this rod moves a sliding rod having a screw at the sliding end so as to fix it at any height; at the other end of the sliding rod is a ring, into which a vessel sits, or may be cemented. This vessel is of glass, having a capacity of a pint or two, and is in the form of a long bottle, contracting at the part seated upon, or cemented into, the ring. It is open above, and also below, but its lower extremity is contracted into a nipple or small-bore muzzle, to which a flexible rubber tube about forty inches in length is to be attached. To the other end of this tube a stop-cock is fixed; upon this a little cup-shaped collar is fastened, and upon this the hard-rubber nozzle is to be fixed. This nozzle should be made to fit the nostril accurately, and should be perforated with four apertures. It is better to have several sized nozzles, to suit different nostrils, and in private practice, each patient should have his or her own nozzle, so as to avoid all possible chances of infection, and ensure cleanliness.

To use the apparatus, fill the glass vessel with the selected fluid, and allow it to pass into the flexible tube as far as the stop-cock; then attach the nozzle, and to make sure that all air is expelled, turn the stop-cock, and allow a little fluid to escape through the

nozzle. Now raise the sliding rod, and fix it at that height which will give the desired pressure. The patient, seated in front of a basin, with his head and face slightly bent over it, is requested to open his mouth slightly and breathe through it exclusively, and to abstain from swallowing. The nozzle is now inserted into one of the nostrils, and held there by the patient's hand of the same side; the little stop-cock is opened, and after a few seconds a continuous and rapid stream of fluid is seen to flow from the opposite nostril into the basin below. Persons who have control over themselves will always bear the injection as here described; but young persons, nervous females, and children become confused, begin to cry, or to swallow and breathe through the nose. In such cases the level of the fluid in the glass should be very little above the level of the external auditory meatus, so that the fluid runs very slowly, or only drops out of the free nostril. The hand of the operator should be upon the India-rubber tube, to close it by compression the moment he sees bubbles come through the nostril, or perceives that the patient swallows or becomes confused.—The higher above the level of the patient's ear the vessel is raised, the greater and more forcible will be the flow; and by lowering it to a level with the ear, it may be so regulated that only single drops at intervals leave the free nostril. In this manner a few ounces of fluid can be made to do the service of pints.

It is always well to let the fluid pass at first under slight pressure, in order to allow the sordes within the nose to be loosened and crusts of dried matter to be softened. When this has been effected, it is useful suddenly to raise the sliding rod and glass vessel, and produce a rapid stream, which will then scour the impurities away. The loosening of crusts and lumps of inspissated mucus is always attended with some irritation, and also with retardation and diminution of the current of fluid. The sudden increase of the pressure, by elevating the sliding rod, is the surest means of causing the least inconvenience to the patient, and effecting in the quickest manner the purpose of the operator.

It is also well to reverse the current now and then, as sordes are much better detached in that manner. If only one nostril is diseased, or the principal seat of the disease, the fluid may be allowed to enter by the opposite side, and to leave by the affected nostril. The current may then be changed, filling the affected nostril, and allowing the current to be discharged by the healthy one; half a dozen changes may thus be beneficially made. This reversal has sometimes the effect of throwing large lumps of inspissated mucus and pus upon the upper side of the soft palate; and as they are too

large to be carried round the septum narium into and through the nasal canal by which the fluid leaves, they are taken into the pharynx, and are immediately ejected by the patient through the mouth. This presence of lumps upon the soft palate is, therefore, sometimes a cause of a sudden interruption of the operation; after their removal, the operation may be continued as before. It is really surprising what an amount of sordes will sometimes be removed from the nose by this rinsing process. Any one who has seen it once will easily conceive the manner in which, by means of these constant accumulations, diseases become chronic, incurable, and lead to fearful suffering and death.

By an examination of the discharges and crusts, under the microscope, we are enabled to determine the part of the nasal cavity from which they come. The upper regions of the nasal cavity are covered by a cylindrical epithelium, which mostly shows two or three layers of cells upon each other. The lower regions of the nasal cavity are lined with a ciliated cylindrical epithelium, the action of which removes particles of dust and fluid toward the nares. When the discharges are purulent, they consist of pus corpuscles only, with hardly any admixture of cylindrical epithelium; this characterizes chronic ulcerations. When these ulcerations become extended, the pus is mixed with cylindrical epithelium which is thus being shed. When the affection of the nose is quite recent, no pus, but only cylindric epithelia are perceived in the secretion. In cases of old follicular ozæna, the crusts have on their soft surface a villous appearance, being condensed mucus, indicating in some slight manner the distribution, size, and shape of the mucous follicles of the Schneiderian membrane. In cases of ulceration with rapid loss of substance, as in specific disease, elements of the deeper fissures, particularly fibrous structures, can be perceived in the discharges. When the nasal cavity is the seat of villous or other descriptions of ulcerated cancer, the elements of these tumors are found in the blackish-brown, thick, and extremely fetid discharges.

Medicinal solutions should be applied at first with the greatest caution, as individuals differ in point of irritability of the nasal cavity; they should be very dilute in the beginning, gradually increasing their strength, after their effect has been well exhausted, by the use of greater quantities applied by a quick flow, or by the use of smaller quantities in a slow current distributed over a longer time of contact.—When the nasal cavity is completely filled with fluid, the sense of smell can no longer be exercised; and the only impingement which the fluids can produce is upon the filaments of sensitive nerves coming from the fifth pair,—but any reflex effects

from the sense of smell are absent. The sensibility of the nasal cavity is about midway between that of the eye and of the mouth; its healthy surface defends itself readily against irritating, chemically-impinging substances, by means of a copious flow of mucus. Ulcerated or excoriated parts lack this power of rapid secretion, and are more readily affected by medicinal solutions than the healthy surfaces. The following are the agents which may be used:

For rinsing the nose, from half an ounce to an ounce of common Salt in a pint of tepid Water, may be used in the quantity of from one to four pints at a sitting. Or Milk, Milk and Water, a Solution of Sugar, etc., may be used. Pure warm water is apt to produce disagreeable sensations, tears, sneezing, a sensation of cold in the head, which may last for some hours, etc. Next to salt, solutions of Phosphate of Soda, Phosphate of Ammonia, and Soda, are advantageous. Their alkalinity has a beneficial influence upon the irritated mucous membrane, and dissolves or loosens any deposits of mucus or pus, which so frequently dry and harden upon the surfaces of the nasal cavity.

To decolorize the nasal cavity, Permanganate of Potassa, one to ten grains to the pint of Water, according to the severity of the case, may be used. It has an alkaline taste, a feeble escharotic action upon healthy, and vascular, or erythematous parts, and forms a faint brownish pellicle over excoriated parts, which dries easily, and upon falling off leaves a healthy surface.

Astringent solutions are, 1. Solution of Alum half an ounce to a quart of tepid Water, in superficial ulceration or blenorrhagic conditions; when used in small quantities, a little Solution of Permanganate of Potassa may be added to it. 2. Solution of Sulphate of Zinc twenty to sixty grains to a quart of tepid water, to which Sulphate of Soda, or Sulphate of Magnesia half an ounce or an ounce, may be added. 3. Solution of Sulphate of Copper, prepared the same as the preceding, No. 2.

Alterative solutions are, 1. Solution of Nitrate of Silver sixteen to thirty-two grains to a quart of Water in which has been previously dissolved from half an ounce to an ounce of Nitrate of Soda.— 2. Solution of Chloride of Gold and Soda sixteen to thirty-two grains to a quart of Water, in which from half a drachm to a drachm of Hydrochlorate of Ammonia has been dissolved. This I have found especially useful in scrofulous and syphilitic ulcerations.—3. Compound Solution of Chloride of Zinc, made by adding to a quart of tepid Water, Chloride of Zinc sixteen to thirty-two grains, Chloride of Gold and Soda eight to sixteen grains; used for the same purposes as the preceding, No. 2.

Styptic solutions are composed of the Tincture of Chloride of Iron, Perchloride of Iron, Tannic Acid, etc., added in sufficient quantity to ice-cold water, with or without the addition of salt, with the first two agents.

Agents which exert a healthy influence on morbid mucous tissues, are, infusions or decoctions of the following articles: Golden Seal, Black Cohosh, White Indian Hemp, Solomon's Seal, Geranium, Witch Hazle, Buchu, etc.—Ten fluidounces of Salt water to which one fluidounce of Cologne water is added, forms a useful stimulating solution.—A very useful tonic and astringent preparation is composed of an infusion of equal parts of pulverized Rhatany Root, Peruvian Bark, and Bayberry Bark.—The quantity of fluid that can be retained in both sides of the cavity of the nose, when a person is lying upon his back, will not exceed from four to five fluidrachms; or, from two to two and a half fluidrachms for each side. Allowing the fluid to escape from the free nostril at the rate of the whole contents of the filled side of the nose per minute, an application of a solution for ten minutes would consume about six cubic inches or somewhat less than three and a half fluidounces.

CHRONIC CATARRH.

Chronic Catarrh, also termed Chronic Coryza, is a very common affection. It is generally the result of an improper treatment of the acute form of the disease, or it may manifest itself after an individual has suffered at various times from acute attacks. It may also exist as a sequence of other diseases, as, measles, scarlatina, etc. The odor from the Damascus and other roses, frequently occasion chronic coryza. It is a disease proper to mucous membranes, and is especially liable to attack those of delicate constitutions, as well as those of strumous diathesis. The disease is frequently very obstinate, continuing for many years, and involving the trachea, bronchi, and even the conjunctiva, occasioning more or less drowsiness, cough, hawking and spitting up of mucus, and emaciation. Sometimes the malady degenerates into ozæna.

The *symptoms* of chronic catarrh, are, more or less irritation of the mucous lining membrane of the nasal cavities, which may extend into the pharynx, larynx, trachea, and bronchial tubes, and which irritation gives rise to a more or less profuse mucus discharge from the nostrils, an unpleasant sensation of fullness or heaviness in the head, sneezing, and a more or less severe cough, which by improper management or neglect, may terminate in phthisis. All the ethmoidal, maxillary, and frontal sinuses, may

be affected. In very troublesome cases, there is a difficulty in breathing through the nose (nasal dyspnœa), and a nasal twang is imparted to the voice, and the slightest exposure to cold exacerbates the disease, causing frontal headache, and if the pharynx and larynx are also involved, occipital headache with more or less soreness of the muscles of the neck. The sense of smell may remain as usual, be impaired, or be completely lost. A catarrhal discharge usually attends nasal polypus, and is frequently the result of an irritation produced by a scrofulous, or syphilitic, etc., local attack, terminating in ozœna, ulceration, or caries, or necrosis of the turbinated bones.

The *rhinoscope* will detect more or less swelling of the membrane, with a deeper red color than natural, and, in some cases, patches of erosion.

As a general rule the *prognosis* is favorable; the unfavorable cases are more commonly those in which the patient neglects attending to the proper measures for its removal.

Where patients laboring under chronic catarrh, are careful to avoid exposures to sudden changes of temperature, or to cold and dampness, it is frequently the case that the malady will gradually disappear, without any therapeutical *treatment*. In other cases, an attention to diet, with moderate exercise daily, regularity of the bowels, and an avoidance of unnecessary exposures, together with the use of some catarrhal snuff, will effect a cure. One of the following mixtures may be used as a snuff: 1. Mix well together two parts each of very finely-powdered Bloodroot, and Bayberry Bark, and one part of very finely-powdered Myrrh.—2. Mix thoroughly together, two parts each of very finely-powdered Bloodroot, Lobelia, and Bayberry Bark, and one part of mild Vegetable Caustic.—3. Mix thoroughly together, very finely-powdered Black Cohosh Root, Geranium Root, Golden Seal Root, each, one ounce, Benzoic Acid, one drachm and a half, Camphor three drachms.

When the disease is severe and obstinate, other measures will be required, as, hydrostatic injections into the nasal cavity with one of the following tepid infusions or solutions, bearing in mind that, when it is suspected that the disease is due to, or is rendered more unyielding by, the presence of a scrofulous or syphilitic taint, those fluids must be preferred which will exert an influence on these maladies.—1. A dilute solution of Chlorate of Soda.—2. A dilute solution of mild Vegetable Caustic.—3. Infusion of equal parts of Black Cohosh, Golden Seal, and Bayberry.—4. Dilute solution of Bromide or Iodide of Ammonium.—5. A dilute solution of Tannic Acid. For other solutions, etc., see page 551. A mixture of one

part of Oil of Turpentine to three or four parts of Sweet Oil of Almonds may be applied to the affected surfaces by means of a small camel's hair-brush, when they can be seen and reached.

Patients of strumous habit of body will, in obstinate cases, require the internal treatment advised for scrofula; those tainted with syphilis, will require the internal treatment recommended for this disease; those subject to rheumatism will require internal treatment for this malady; and those laboring under hepatic disease, or derangement of the digestive organs, will require a suitable treatment for the removal of these complications. In many instances it will be a matter of astonishment, to observe how rapidly a previously intractable catarrh will be cured, after its complications have once been properly treated.

Among the several conditions which may be the result of chronic catarrh, (but which may sometimes originate from other causes). are the following :

1. *Hypertrophy of the nasal mucous membrane* is sometimes met with among feeble and strumous persons, especially children; and occasionally it may extend throughout the whole membrane of both nostrils. It usually comes on gradually, interfering more or less with nasal breathing, which is much worse during cold and wet weather, and may exist for years; sometimes it disappears without treatment. Upon an examination, the mucous membrane will be found tumefied, soft and vascular, usually covered with mucus or muco-pus, and somewhat resembling a polypus, for which it may be mistaken; but it may readily be determined from this tumor, by its situation, its deeper red color, and in not being pedunculated. Mr. Ure states that it is frequently limited to that portion of the mucous membrane which folds back and lies underneath the inferior turbinated bone. The mucous membrane at the border and posterior part of this bone is naturally thick, from the abundance of venous plexuses in the interior. The bone sometimes becomes involved in the disease.—The *treatment* consists in constitutional antistrumous remedies, and local applications of strong Solution of Nitrate of Silver, Solution of Sulphate, or Chloride of Zinc, of Sulphate of Copper, of Alum, of Nitrate of Uranium, of Iodide or Bromide of Ammonium, of Chloride of Gold and Soda, of Tannic Acid, of Perchloride or Persulphate of Iron, etc.—When the hypertrophied parts can be seen and reached, the mixture of Oil of Turpentine and Sweet Oil of Almonds, heretofore referred to, may be used with benefit.

2. *Loss of the sense of smell* may not only arise from catarrhal inflammations of the nasal mucous membrane, but sometimes orig-

inates from chronic cerebral diseases, syphilis, typhoid and exanthematous fevers, etc. When the result of inflammations, or febrile diseases, and not associated with syphilis or affections of the brain, it may frequently be cured by the persistent use for a long time of local tonics and stimulants by injections with hydrostatic pressure, and the internal administration of Quinia, Strychnia, Alcoholic Extract of Black Cohosh, Belladonna, etc.

3. *Perversion of the sense of smell* may be occasioned by various causes, as, derangements of the digestive apparatus, organic cerebral affections, syphilis, uterine affections, hepatic maladies, etc., and sometimes it is a premonitory symptom of epistaxis, apoplexy, or, paralysis. Sometimes, it precedes caries. In most cases, however, it is due to impaired nervous power, resulting from local congestion of some part of the Schneiderian membrane. Certain odors can not be distinguished, and in some instances, the persons affected will experience an unpleasant odor in their own nasal organs, which can not be detected by other persons. It may or may not be associated with follicular laryngitis, by extension of the disease. An examination will reveal a relaxed condition of the mucous membrane of the parts affected, with follicular enlargement, and an abnormally deep-red color, especially of the membrane covering the inferior turbinated bone.—The local *treatment* will be applications or showers of Nitrate of Silver, Tannic Acid, or Sulphate of Iron, etc., in solution; or, hydrostatic injections of the articles named in the preceding paragraph; and which should be used in conjunction with the constitutional treatment named for Follicular Laryngitis. Alkaline solutions introduced by hydrostatic injections, will often be found very beneficial.

4. *Ulcers of the nasal fossæ* may exist with or without much discharge. When a discharge is present, and is of a fetid odor, the disease is named *ozæna*. These ulcers may be the result of frequent catarrhal inflammatory attacks, and may also be associated with, and even be due to, struma, or syphilis. The ulceration may commence in the anterior part of the nose, upon the lower turbinated bone, or upon the nasal septum, and may gradually extend the whole length of one or both nostrils. It may also extend in depth, involving the various subjacent structures. And sometimes it may be associated with ulcerations of various portions of the pharynx, uvula, soft palate, etc. *Rhinosecopy* will detect the tumefied, congested, vivid, red, and ulcerated surfaces in the pharyngo-nasal cavity, and posterior-nasal fossæ, as well as any destruction of the turbinated bone, or of the nasal septum. Both constitutional and local *treatment* will be required, adapted to the peculiar character of

the ulceration ; the several means named under Ozæna may be had recourse to, as they may be indicated.

EPISTAXIS.

Epistaxis or Hemorrhage from the Nose is of common occurrence, and may be met with at any period of life. The frequent disposition of the nasal mucous membrane to hemorrhage is due to its great vascularity, the blood exuding principally from the capillaries. Young persons, especially girls, are more subject to nose-bleedings than those of advanced age ; and, frequently, when it occurs among the latter, especially when frequent and profuse, it is the premonitory indication of paralysis, apoplexy, or other grave disease.

Epistaxis may be *caused* by any circumstance that will derange the circulation and favor an increased flow of blood to the head, as, fits of passion, violent mental excitements of any kind, long-continued study, severe mental application, active or laborious exercise, fatigue, application of cold to the feet, overeating, violent coughing, exposure to the direct rays of the sun, a sudden or long-continued stooping posture, tight clothing around the neck or body, playing on wind-instruments, intemperance, suppression of accustomed evacuations, etc. It may also be occasioned by the application to the nostrils, or nasal inhalation of irritants and stimulants, also, by blows, falls, picking the nose and abrading its delicate lining membrane, etc. In dyscratic epistaxis the bleeding is frequently owing to erosion or ulceration of this membrane.—Chronic vascular ulcers on the turbinated bones, sometimes occasion the hemorrhage.

Not unfrequently, epistaxis occurs as a critical discharge, as, in apoplexy, amenorrhea, commencing fevers, etc., in which instances it may prove salutary, and should not be checked too suddenly, unless very profuse. When it happens during the latter stages of typhoid fevers, in jaundice, anemia, scorbutus, etc., it is then due to a loss of tone of the vessels of the Schneiderian membrane in conjunction with an abnormal state of the blood, and may prove troublesome and even serious. Sometimes the flow is dependent upon cardiac, hepatic, splenic, or other organic affections.

The *symptoms* of epistaxis are readily recognized. The hemorrhage may suddenly manifest itself without any premonitory symptoms ; or it may be preceded by heat and itching or tingling in the nostrils, pain and weight in the head, dizziness, tinnitus aurium, flashes of light before the eyes ; flushed countenance, throbbing

of the temporal or carotid arteries; though it must be recollected that pale and delicate persons are also very apt to suffer from epistaxis. In the passive form there is seldom any precursory symptoms, the slightest touch or least local irritation producing the hemorrhage. Persons who suffer constantly from cold feet, constipation, and slight chilliness, are also apt to be attacked with this form of bleeding.—Generally, the blood flows from one nostril only; but it may be discharged from both, especially when of a serious nature. The quantity discharged may be limited to a few drops or a few drachms, or it may be very profuse, continuing for several days, or carrying off the patient in a few hours, and which is more frequently observed in the passive form of the hemorrhage. The periods of return of the flow, will vary from a few hours, to several days, weeks, months, or even years, and these may occur regularly or very irregularly.

The *prognosis* of epistaxis occurring in healthy persons is generally favorable; but when it affects those laboring under scrofula, syphilitic taint, disease of the heart, brain, or other organs, the prognosis is more or less unfavorable, and must be governed by the circumstances of the case, and the positive or negative influence derived from treatment. When it occurs in advanced years, especially among persons who were not disposed to it previously, it is very apt to be the forerunner of some serious attack. When it occurs during jaundice, or other asthenic maladies, the blood being thin, dark, non-coagulable, and the flow not influenced by remedies, it is very apt to prove fatal.

Treatment. As a general rule, epistaxis requires but little medical interference. Instances, however, occur, in which the hemorrhages are profuse, and frequently repeated, and, when they are not vicarious, measures should be taken to promptly check them. All ligatures, cravats, or tight clothing around the neck, limbs, or body, must be loosened or removed, the patient be kept quiet and in a sitting posture; cold applications, as, cold water, ice, etc., should then be applied to the forehead, nose, and nape of the neck. Should this fail in arresting the flow, various other means, which have been found efficacious, may be adopted, as, for instance, external pressure upon the nose, so as to close the nasal passage for a few minutes; plugging the nostrils with cotton or lint saturated with some astringent fluid, as, infusion of Geranium, or of Marsh Rosemary; Solution of Tannic Acid, Perchloride of Iron, Persulphate of Iron, Tannate of Iron, or, Sulphate of Zinc; elevating the arms in a vertical direction and retaining them in this position for a sufficient length of time, etc.—Patients subject to

these hemorrhages should have their bowels kept regular; the surface of the body should be bathed daily in cool water; and a shower bath, or a pitcher of cool water should be poured upon the back part of the head, and along the spinal column, every morning, drying at once with considerable friction.

When the hemorrhage is abundant and obstinate, not yielding to the means above named, it may become necessary to thoroughly plug the nose throughout its entire passage from the anterior to the posterior nares, with lint or cotton moistened with an astringent. For this purpose, Bellocq's canula will be found a very useful instrument. Upon a similar principle, the introduction of a small bladder, or intestine of a pig, was recommended by the late Prof. W. B. Powell. The agent introduced, should be allowed to remain for three or four days, or until the discharge has permanently ceased. These means should be assisted by measures calculated to divert the circulation to the inferior extremities, as, catharsis, stimulating warm pediluvia, cold applications to the head, etc.

When there is a morbid alteration of the blood, as, in scurvy, jaundice, etc., in conjunction with the means already named, the appropriate remedies to combat the unhealthy condition of the blood must be pursued,—as, the internal use of Sulphite of Lime, Hyposulphites, preparations of Iron, Tannic Acid, Oil of Turpentine, Citrate of Potassa, Bitartrate of Potassa, and alterative remedies—according to the peculiar morbid condition of the blood, or, to the character of the affection to which the hemorrhage is due.

The nose is subject to other affections, principally of a surgical character, which only require a passing notice; they are as follows:

1. *Polypus*, of which several kinds are described by authors, all of which may, however, be comprised under the following heads, viz.: *a. Soft*, or *gelatinous polypus*, of a yellow, yellowish-white, or greenish color, slightly vascular, and somewhat translucent, with a narrow base or neck, but which is occasionally very broad, and growing from the mucous membrane. It is usually attached to the superior and external wall of the nostrils, but occasionally proceeds from the ethmoid cells, the lower meatus, or the thick membrane covering the inferior turbinated bone; it is seldom or never met with on the septum. The *rhinoscope* can usually determine its true position, as well as of any other growths that may present at the posterior nares and pharyngo-nasal cavity. The symptoms observed in polypus are the same as those of other affections interfering with

the integrity of the nasal passages. The *treatment* is, to carefully remove them by torsion and avulsion, by means of a polypus forceps, or a double canula with silver ligature. After which the nasal cavity may be injected by hydrostatic pressure, with some fluid preparation calculated to remove morbid action and impart tone to the mucous membrane, as, a very dilute solution of Tannin, of Sulphate of Zinc, or of Bichromate of Potassa, etc., repeating the injection every day or two for several weeks. When the polypus can readily be reached, the application of a saturated solution of Bichromate of Potassa to the accessible portion of it, has in the course of a few days occasioned an inflammation, which sometimes has extended to the nose, and shriveled up the polypus.

b. Hard, or fibrous polypus, of a purplish or dark red color, composed of fibers, and vessels (so that hemorrhages are frequently present), with a broad base, and attached to the superior turbinated bone, the nasal septum, or the nasal floor. As with the preceding form, it sometimes attains considerable size, giving rise to the deformity known as *frog-face*. Generally, but one polypus exists, though it is more apt to return, after having been removed, than the soft polypus, and is much more to be feared than this. The most formidable polypus is the naso-pharyngeal, which springs from the basilar process of the occipital bone. Fibrous polypus may become malignant. It requires removal by a surgical operation.

c. Malignant, or cancerous polypus, which can only be treated by palliative means.

2. *Calcareous concretions*, or *rhinolithes*, are very rarely met with, and may be detected by inspection, or, by contact with a probe occasioning a dead clicking sound. There may be one or several of them, which may be removed by a hook, or polypus forceps; when covered with mucous membrane, this will first require division, before attempting the extraction of the nasal calculi.

For *Malformations, Tumors of the Nasal Septum, Abscesses, Occlusion and Contraction of the Nostrils, Foreign Bodies in the Nose*, and *Diseases of the Frontal Sinuses*, the reader is referred to works on Surgery. The third volume of "Holmes's System of Surgery" contains much valuable information on nasal diseases, from the pen of Mr. Alexander Ure.

DISEASES OF THE THROAT AND AIR PASSAGES.

FOLLICULAR PHARYNGO-LARYNGITIS.

This disease has also been termed "Dysphonia clericorum," or "Clergyman's Sore Throat, Granular Pharyngitis, Papillary Sore Throat, Tubercular Disease of the Fauces and Larynx, and Follicular Disease of the Pharyngo-laryngeal Membrane." It consists in a chronic inflammation of the mucous follicles of the pharynx extending into the larynx, and sometimes into the trachea and esophagus, and is frequently associated with a similar condition of the mucous membrane of the pharyngo-nasal cavity, and a moist chronic bronchitis. It is more frequently met with among males than females, in the proportion of seventeen to five; and is more frequent between the ages of fifteen and thirty, though when once manifested, it may continue for years, unless removed by treatment.

One very common *cause* of this disease is, exposure to sudden vicissitudes of temperature, giving rise to frequent "colds in the head," or catarrhal affections of the throat and air passages; in my own practice I have found it more especially present among strumous persons, those suffering from rheumatism, and those addicted to sexual excesses or masturbation. It is frequently due to derangements of the digestive organs, to influenza, and to exanthematous diseases. Over-exercise of the vocal organs, either in speaking or singing; exercise of the voice while laboring under influenza or a catarrhal inflammation; and public speaking in cool or cold places, having the head uncovered, are among the exciting causes of this malady. It may likewise be produced by inhalation of the fumes or dust of acrid substances, and appears to be a common and obstinate affection among persons inhaling limestone dust, as in towns and cities where the streets are paved with limestone rocks. It often coincides with anterior herpetic eruptions, and patients are sometimes troubled with acne; it is also frequently combined with abdominal plethora. Excessive tobacco smoking is a frequent cause, and with some persons, even very moderate smoking will give rise to it, if persisted in.

The first change observed is an enlargement of the follicles of the pharynx, and perhaps, also, of the pillars of the fauces, of the uvula, of the back of the tongue, of the tonsils, and of the larynx. In the early period of the disease, the follicular enlargement appears like minute red points disseminated over the abnormally reddened mucous membrane; and as the disease insidiously and slowly

advances, these points gradually increase in size, become discoid or ovoid, glistening, and frequently covered over with a thick, adhesive mucus, which must be removed before their condition can be observed. The mucous membrane is unnaturally red, tumid, appearing lax, and thickened from mucous infiltration; patches of erosion may sometimes be observed in those parts where this membrane has been deprived of its epithelial covering. As the disease progresses, the enlarged follicles become indurated, or ulcerated, or secrete a muco-purulent fluid, or become the seat of tuberculous deposit. When the ulceration is extensive, the submucous tissues become involved. If the disease be allowed to progress without treatment, it will more or less gradually produce serious lesions, some of which will be referred to hereafter.

In connection with this disease, there may be elongation and enlargement of the uvula, enlarged tonsils, chronic bronchitis, erosion and ulceration of the epiglottis, and, phthisis with the tuberculous form of the follicular affection, etc.

The *symptoms* vary somewhat with different persons, owing, probably, to the location, degree, and extent of the malady, which may exist for some time without the patient's attention being called to it. A dryness of the throat may be the first symptom observed, from an altered or arrested secretion; or there may be an irritation or tickling sensation in the throat, giving rise to frequent attempts to clear the throat of mucus, by hawking, hemming, or by what is termed a "short hacking cough," and, perhaps, an inclination to swallow. There is also a huskiness or hoarseness of the voice, which is much aggravated by any kind of vocal exercise, with a sensation of more or less irritability of the throat, and which public speakers often endeavor in vain to remove by repeated draughts of water, which only give momentary relief. Among singers a loss of the clearness and sweetness of voice is observed, as well as of one or more notes. As the disease continues to advance, there will be a more or less profuse secretion of mucus, or of a muco-purulent fluid, opaque, of an acrid, very viscid and adhesive character, and proving a source of great irritation; sometimes, however, the mucous membrane will continue dry and irritable, annoying the patient very much. A feeling of constriction in the fauces is usually experienced; the voice may be harsh, hoarse, whispering, and in some cases there will be a complete aphonia.

In a somewhat advanced state of the disease, the irritation or tickling sensation of the throat, as well as the hemming or hawking, will be worse in winter than in summer, and the expectoration will generally be more copious and troublesome in the morn-

ing. Patients who do not dry their feet by a fire, in cold weather, before retiring to bed, or who expose their bare feet to cold floors, are apt to have the irritation augmented for the time being. Frequently, after a prolonged silence, on attempting to speak, there will be an inability to produce a proper sound until the throat has first been cleared of the offending tenacious mucus, by hemming or hawking. The expectoration, at first, is of the character of mucus, then becomes white and frothy, and in the advanced stages it may be streaked with dark or bluish spots or masses, or with more or less blood. In some rare cases, there may be considerable hemorrhage. Passing from a warm to a cold atmosphere or room, often augments the existing irritation, occasioning a short hacking spasmodic cough, and more or less difficulty of breathing; the same symptoms may occur when the patient walks against the wind, or is exposed to dust from sweeping a room, or arising from the streets or roads. The symptoms are almost always aggravated in cold, damp weather, so much so, that it is very common for the patient to suppose that he has contracted a "fresh cold." Cough is by no means a necessary symptom of the disease, and when it is present it is rarely of a marked character, being short and spasmodic, or more like a sudden hawking to clear the throat, and is due to the laryngeal irritation, when this is considerable; when the lungs or bronchi are affected at the same time, a more decided and annoying cough will ordinarily be present.

Several, or all of these symptoms may be present in any one person, and continue through life without causing any alarm, except when hoarseness and spasmodic cough have followed some unusual effort of the vocal organs. Sometimes they disappear entirely, returning only when the organs are tasked too much, or when a cold has been contracted.—If the disease is allowed to advance there will be constitutional symptoms, as, impaired digestion, acceleration of the circulation, dry and rough skin, unequal temperature of the body, debility, emaciation, night sweats, etc., together with other lesions.

If the thyroid cartilage be pressed slightly between the thumb and finger, it will occasion pain or soreness; and the same result will follow if the glands or muscles along the sides of the neck be compressed between the thumb and finger, grasping both sides of the neck at the same time. The *laryngoscope* will reveal various conditions, according to the stage and extent of the disease; the mucous membrane of the pharynx and larynx will be found more or less abnormally red, relaxed, swollen, and thickened, and studded with minute red points, or prominent tumors, together with patches

of erosion or ulceration; there may also be a congested condition of the base of the tongue, and of the epiglottis; the latter being sometimes so far depressed backward or pendent, as to prevent an inspection of the larynx, or, it may be thin, dry, ulcerated, etc. In the larynx, the mucous lining membrane may present a similar congested and dotted appearance, and the vocal cords will be found to have lost more or less of their white color, varying from a gray color tinged with pink to a vivid redness, and the ventricular (false) cords may be considerably swoln. A tenacious fluid will usually be observed covering more or less of the affected membrane.

The *prognosis* of follicular pharyngo-laryngitis is generally favorable; except, when the disease has degenerated into some of its more serious consequences, referred to hereafter. The earlier the period at which the treatment is undertaken, the more prompt will be the cure.—The *pathological appearances* will resemble those observed during life, together with such other changes as may have been effected by the disease, and which need not be repeated here, as they will be described in their appropriate places.

In the milder forms of this affection local *treatment* alone will generally suffice; in the more advanced stages both local and constitutional measures will be required. In the earlier and milder forms, inhalations of the vapor of dilute Acetic Acid, together with frequent garglings of the throat with a mixture of Vinegar, soft Water, each, one gill, Salt a teaspoonful, and an absolute quietness of the voice for some time, will frequently remove the disease. Or, gargles of Borax and Alum; Sulphuret of Potassa; Chlorate of Potassa; Hydrastis and Cimicifuga; Sulphate of Iron; Cimicifuga and Geranium; Tannin; Hamamelis; Statice, Hydrastis and Capsicum, etc., in solution or infusion, may be used with benefit.

The careful application to the throat and fauces of a mixture of one part of Oil of Turpentine and three or four parts of Oil of Sweet Almonds, will frequently be followed by the happiest results. So will inhalations of the vapor of Oil of Turpentine, which in some instances may be improved by the addition of a very small amount of Chloroform. This will be found very efficacious. Medical men appear to be so wholly attached to nitrate of silver in this and other mucous diseases, that they overlook the fact that there are other agents fully as useful, and, in many instances, greatly superior to it.

In the more severe forms, other agents may be required, being introduced upon the affected parts in the form of powder, or solution. The powders usually employed are those of Alum; Sulphate

of Copper one part to ten parts of Sugar of Milk, or of Lycopodium; Sulphate of Iron one part to ten parts of Lycopodium; Chloride of Gold and Soda one part to forty parts of Sugar of Milk; Nitrate of Silver one part to two, three, or four parts of Sugar of Milk, etc. Place a small quantity of the mixture to be used, say a drachm or two, in the form of an impalpable powder, into a wide mouth glass jar capable of holding a pint or a quart; this must then be well closed with a cork holding one vulcanized rubber tube for the mouth, or two for the nostrils. The tube inserted into the cork for the mouth may have a diameter of three-fourths of an inch or an inch; those for the nostrils may be of the same diameter, but the nasal ends should gradually taper off, so as to fit the nostrils. The bottle being well shaken so as to fill its atmosphere with the very finest particles of the powder, the patient will immediately place the tube in his mouth, or the tubes in his nostrils, and take three, five, or ten deep inspirations, which will carry the dust into the larynx, and even into the lungs, sprinkling the air passages in its progress lungward. And this may be repeated as required, two or three times a week. The important point in this inhalation is, to have the powders, the bottle, and the tubes quite dry, and perfectly free from moisture, which may be done by keeping them in a dry and warm place, after having once well dried them.

If the articles are used in liquid form, they may be injected into the larynx by means of the graduated laryngeal syringe, the laryngeal fluid pulverizer, or the fluid pulverizing instrument, which reduces a fluid to so fine a spray or vapor, that it can be readily conveyed even to the air-cells of the lungs by deep inspirations. These instruments can be had of any surgical instrument maker.

Or, the remedies may be directly applied to the interior of the larynx, by means of a large, full-bellied sable hair, camel's hair, or squirrel's hair-brush, placed upon the extremity of a bent whale-bone. The use of the sponge probang I have entirely dispensed with, the brush answering the same purpose, and producing less irritation. By means of the laryngeal mirror, the brush may be passed into the larynx to the vocal cords, around the base of the epiglottis, or upon any other part of the throat that may be required. And in cases where the brush can be directly applied to the diseased surfaces, it is probably of more value than any other plan that can be adopted, as there is no risk or danger whatever in applying it to the delicate parts of the air passages.

When a solution of Nitrate of Silver is used, it should be in the

proportion of from forty to sixty grains of the crystals of the silver salt to the fluidounce of distilled water. A solution of Chloride of Lime, or of mild Vegetable caustic, five to fifteen grains of either agent to the fluidounce of water, will often answer a better purpose than the Nitrate of Silver solution. Various substances dissolved in Glycerin, have likewise been used, applying them by means of the brush, as, Nitrate of Silver, Perchloride of Iron, Alum, Sulphate of Morphia, Sulphate of Strychnia, Iodide of Ammonium, Bromide of Ammonium, Chloride of Gold and Soda, Iodide of Silver, Tannin, Chloride of Zinc, Nitrate of Uranium, Sulphate of Copper, Sulphate of Zinc, Iodine, Nitric Acid, etc. The advantage in using Glycerin is, that it adheres more persistently to the mucous membrane, than aqueous fluids, and consequently keeps this membrane under the action of the dissolved agent for a much longer time. Borax and Glycerin is recommended for healing ulcers at the root of the epiglottis.

When it is desired to apply solid caustic to an ulcer, growth, or other morbid condition of the larynx, this may be done by means of a laryngeal caustic-holder, which is so arranged that, after touching the part, it is immediately withdrawn into its sheath. A small stick of Nitrate of Silver may be attached to its cauterizing extremity, or, a small smooth piece of soft wood, moistened with concentrated Nitric Acid. This may be applied to any part of the larynx, by the aid of the laryngoscope, just barely touching the part.

Counter-irritation to the external surface of the throat, directly over the larynx, will always be found useful. The Compound Tincture of Camphor may be well rubbed upon the parts every night and morning; or, a pustular eruption may be produced by the application, two or three times a day, of a liniment composed of Olive Oil, Oil of Turpentine, each, two fluidrachms, Oil of Origanum four fluidrachms, Croton Oil one fluidrachm; mix. In very severe and obstinate cases, and especially when there is aphonia, the Compound Tar Plaster applied alternately to the throat and back of the neck, so as to keep up a constant discharge from one or the other locality, will prove serviceable.—If the uvula is enlarged and elongated, a portion of its inferior extremity should be excised, in order to lessen irritation. Enlargement of the tonsils, if not removed by local applications, will also require to be excised.

Edema of the epiglottis frequently occurs in this affection, and is generally attended with difficulty of swallowing, aphonia, occasionally ulcerations both of the larynx and epiglottis, and in a few

instances with destruction of the cartilages. It may be reduced by applications of strong solution of Nitrate of Silver from time to time, in conjunction with Iodine and Iron. In obstinate cases, small scarifications made with a proper instrument, assisted by the laryngoscope, will afford prompt and decided relief.

The constitutional treatment consists in the internal employment of the Compound Syrup of *Stillingia* with Iodide of Potassium, or the Iodine Pill, Iodide of Ammonium, Bromide of Potassium or Ammonium, etc.; in conjunction with a lozenge composed of Hydrastin, Geraniin, and Cimicifugin, or, the Compound Troches of Liquorice.—In the earlier periods of the disease, one of the following preparations will be found very efficacious; the dose of either should be allowed to pass slowly down the throat: 1. Take of Canada Balsam one drachm, Oil of Cubebs two drachms, Oil of *Stillingia* fifteen minims, Alcohol two drachms; mix, and triturate well together. The dose is five or ten drops on sugar, repeated three or four times a day. 2. Take of Compound Syrup of Spikenard six fluidounces, Fluid Extract of *Stillingia* two fluidounces, Iodide of Potassium two drachms; mix. The dose is a teaspoonful or two, to be repeated three times a day.

The bowels must be kept regular by small doses of Podophyllin and Leptandrin, or, of Iridin and Leptandrin, which may be given in the form of powder, triturated with sugar, or, in pill form; and the skin must be strictly attended to, by repeated bathings, frictions, and an occasional Spirit Vapor Bath. If the digestive functions are disordered, the appropriate treatment must be pursued therefor. The diet must be especially regulated, avoiding all acrid, irritating, and indigestible aliment, as well as all articles that disagree with the stomach. Dusty and vapory places must be avoided, as well as exposures to damp and windy weather; moderate exercise should be taken daily in the open air. Reading aloud must be prohibited, as well as public speaking, or much talking. In summer, cold douches to the throat and neck may be used as adjuncts.

CHRONIC LARYNGITIS.

Chronic Laryngitis may be primary, or it may follow acute laryngitis; very frequently it ensues as the consequence of several diseases of the throat, especially follicular pharyngo-laryngitis. The disease is a very common one, and is apt to involve the lungs by sympathetic irritation and extension, especially among weak and scrofulous persons. Males are more subject to it than females. Its duration varies from a few weeks to several years.

The *causes* of chronic laryngitis are the same as those of follicular pharyngo-laryngitis. It is frequently dependent upon tubercular phthisis; while again, where there is a predisposition to consumption, the irritation of the lungs induced by the laryngitis, may hasten the pulmonary tuberculosis. Mercury, syphilis, foreign bodies in the larynx, and injuries of the throat, may also give rise to chronic laryngitis.

The *symptoms* of chronic laryngitis are generally very insidious, progressing so gradually, that frequently the disease has advanced to a serious extent, before the patient bestows any particular attention to it, or manifests any anxiety regarding its treatment. Many of the symptoms present in follicular pharyngo-laryngitis, are also present in chronic disease of the windpipe, being due in the former affection to the laryngeal complication. In the milder cases, there will be experienced a slight irritation or tickling in the throat, giving rise to a hawking, or short hacking cough, often followed by expectoration of more or less mucus, and which act occurs so frequently, especially when the patient is speaking, that he is hardly aware of it. This irritation is augmented by inhaling cold air, or dusty particles, by catarrhal inflammations, by sudden changes from heat to cold, and by prolonged or energetic vocal exercise.

The physician is, however, rarely invoked to treat the milder form, it is generally only in the stage of ulceration when his assistance will be sought, and then the symptoms are usually well marked. There will frequently be a dryness of the throat, with considerable irritation or tickling; the voice will be materially altered, being either rough, cracked, hoarse, squeaking, whispering, enfeebled, or completely lost. A sense of uneasiness or pain is felt in the larynx, which may be limited to a small space, or extend over the larynx; and pressure upon the thyroid cartilage will occasion soreness or pain. From the irritation induced by extension of the ulceration, the small laryngeal muscles contract spasmodically, causing a partial or complete approximation of the lips of the glottis, and a constriction at the laryngeal orifice, which affects respiration, causing much difficulty of breathing and cough. The cough is at first dry, short, and hacking; but at a later period, and when the glottis is incapable of being closed, it is loose, continuous, of a peculiar, jerking, hawking character, of high pitch, and followed by expectoration of more or less mucus, sometimes mixed with pus or blood. It will be noticed that it is rarely the case that a coughing fit occurs in this affection, unless it has been immediately preceded by a quick, short, and deep inspiration. The sensibility of the larynx is always more or less increased, and which is principally ob-

served in the fact that cough is readily excited by cold applied to any part of the body, but especially to the soles of the feet, the throat, and upper part of the back; indigestible substances in the alimentary canal, irritants, constipation, inhalation of dust or dry air will also occasion cough. The respiration is generally more difficult at night, and after any physical exertion; and, according to the degree of œdema of the glottis, or approximation of its lips, it may be hissing, whistling, stridulous, or suffocative. When the epiglottis is affected, there will be difficulty of swallowing, and a disposition for particles of food to fall into the glottis.—Epiglottic ulceration, ossification of the cartilages, and the other more serious consequences of the disease, will be treated upon separately.

In the advanced stage of the disease, hectic fever, night sweats, constant irritating cough, profuse expectoration, emaciation and debility are present, which symptoms so strongly resemble those of phthisis, that the disease has been called “laryngeal phthisis.” A careful examination of the chest will reveal whether the laryngeal malady be accompanied or not with tuberculosis of the lungs.—When the disease proves fatal, it is either from severe irritative fever, asphyxia, or pulmonary consumption.

An examination by the *laryngoscope* will reveal various appearances, according to the locality and extent of the disease. In many parts of the larynx, the tissues will be observed thickened and indurated from submucous and interstitial deposits of serum, lymph, or albumen; the mucous membrane may be slightly injected, or may possess its natural pale color, but its surface will be rough, irregular and hardened. Ulcerations of variable size, shape, depth, and location may be discovered. The ventricular or false cords are frequently ulcerated, especially on the borders of the ventricles, and to which organs the ulceration often extends. The vocal cords may also be ulcerated, but much less frequently than the ventricular. If the ulcer is seated at the junction or anterior part of the vocal cords, both speaking and coughing will produce soreness and uneasiness; if the anterior or lingual surface of the epiglottis is ulcerated, there will be pain or difficulty in swallowing. Ulceration between the arytenoid cartilages frequently gives rise to vomiting, by reflex irritation. Generally, but not invariably, when the lungs are sound, the ulceration is confined to that part of the larynx *above* the vocal cords; though all parts of the laryngeal surface may be affected by ulceration, extending downward to the trachea and bronchi. Old and extensive ulcerations frequently present a number of soft, reddish, vascular elevations, which have been termed “caruncles.” Sometimes ulceration may destroy one or both of the vocal

cords, giving rise to incurable aphonia,—the same result will occur when the vocal cords are permanently separated, with an entire loss of action, deep red color of their mucous covering, and immobility of the arytenoid cartilages. Syphilitic ulcerations usually have a sloughy base. Other morbid changes may also be observed, but they will be specially referred to hereafter. The above are the chief appearances presented by the laryngoscope, in the malady under consideration.—In the examination of the larynx after the cure of extensive ulceration, the general cavity of this organ will be found contracted and irregular, and the vocal cords will have lost their natural appearance.

Associated with the above-named conditions, the mucous membrane of the pharynx may be found thickened and indurated from subjacent deposit, and this may extend to that covering the velum palati, with, probably a loss of some part of its substance, or, perhaps its adhesion to the back part of the pharynx. In other instances, we may find an enlarged or cavernous throat, from atrophic contraction of the pharynx, the result of augmented absorption.—The *pathological appearances* confirm those observed with the laryngoscope.

The *prognosis* of chronic laryngitis is favorable in its simple and mild forms; yet it must be borne in mind that where the disease has once manifested itself and been cured, there is always a subsequent predisposition to its return upon even a slight exposure to its causes. Ulcerations may be healed when of not too long standing or too extensive; the prognosis, however, is less favorable in scrofulous and weakly constitutions, or where there is a disposition to phthisis. The more extensive the ravages of the disease the more unfavorable is the prognosis. And when the laryngeal disease is consecutive upon pulmonary tuberculous excavations, it is incurable. Syphilitic ulceration is frequently curable, especially when the local lesion is not very extensive, and the constitution has not become enfeebled.

The *treatment* of chronic laryngitis, like that of follicular pharyngo-laryngitis, is both local and constitutional. The local measures consist in the application of powders or medicated fluids to the diseased surfaces, by the means named under the treatment of the preceding disease referred to. Wherever ulceration is to be seen, a strong solution of Nitrate of Silver (more commonly forty grains to the fluidounce of distilled water), should be applied to it every day or two by means of the curved brush, aided by the laryngoscope; and the same application should be made to any abnormal appearance in the fauces or pharynx. Or, concentrated Nitric Acid

may be touched upon the ulcerated surfaces, by means of a soft piece of wood moistened with the acid, and fastened into the laryngeal caustic-holder. This course must be persevered in until the ulcers have healed. Frequently, an improvement in the voice will be observed after the first two or three applications, provided the vocal cords and their necessary appendages have not been permanently impaired. If the remedial agents can not be applied in this manner, then some of the other methods referred to under Follicular Pharyngo-laryngitis may be pursued.

Counter-irritation externally over the larynx, or along the sides of the neck, should also be produced, either by rubefaction, pustulation, or suppurative discharge. Excessive irritation, cough, or tendency to spasm of the glottis, may be relieved by the inhalation of some anodyne vapor; and, in many instances, much benefit will be derived from a Belladonna Plaster, or Compound Plaster of Belladonna, worn over the larynx.

The constitutional treatment will be the same as that named under Follicular Pharyngo-laryngitis. Syphilitic ulcerations may be treated locally by Nitrate of Silver, or Chloride of Gold and Soda, in solution, or by Nitric Acid, together with the internal treatment recommended for Constitutional Syphilis.

After the ulcers have healed, there may remain a thickening and weakened action of the vocal cords, with or without dyspnoea, on exercise; an absorption of the interstitial deposit occasioning these symptoms will be followed by permanent relief. This may be effected by the internal use of the Iodide or Bromide of Potassa or of Ammonium; Croton Oil Liniment, or Compound Plaster of Belladonna over the throat and larynx, externally; and the daily local application of the following solution, by means of a suitable sized curved brush.—Take of Chloride of Gold and Soda four grains, Hydro-chlorate of Ammonia eight grains, Distilled Water one fluid-ounce; dissolve the salts in the water. Inspiring Ammoniacal vapor, not too strong, will also be found advantageous, as well as the vapor from Oil of Turpentine.

The general management of the patient, hygiene, etc., will be the same as advised under Follicular Pharyngo-laryngitis.—When some of the more serious complications, to be presently considered, are likely to arise, it has been recommended to make a fistulous opening into the *trachea*, and to keep it constantly patulous; this will afford rest and quiet to the vocal organs during their treatment with the local medications, and, the voice can be restored whenever a finger is placed over the fistulous orifice. This course is said to

have saved the lives of several patients, and has even permitted cures to have been effected; I know nothing of it from experience.

Before closing this article, I would state that in one case of Chronic Laryngitis with ulceration, I applied upon the ulcers by means of a small brush, a mixture of one part of Oil of Turpentine and six parts of Oil of Sweet Almonds. It did not create the amount of irritation I had looked for, and in the course of twenty or thirty minutes after each application, it produced a prolonged relief of all the distressing symptoms. Continuing its use, a permanent cure was effected. I do not know how this may act in other cases, but if as favorable as in the one just referred to, it will become an important and valuable agent in the treatment of this class of diseases, and perhaps, even, in pulmonary phthisis.

It may be proper to again state that all the various laryngeal diseases herein referred to, are frequently associated with tubercular phthisis, either primarily or secondarily. If the disease is primarily seated in the larynx it may extend to the lungs; or, if originally located in the lungs, it may advance upward, producing ulceration, etc., of the larynx. In this association of laryngeal and pulmonary disease, the ulcerations of the former are almost invariably of a tuberculous character; and, like tuberculous ulcers generally, however minute they may be at the commencement, they more or less rapidly extend in width and depth, occasioning fearful ravages. The laryngeal surface of the epiglottis, the larynx, vocal cords, and trachea, are all subject to the attacks of this tubercular ulceration; and, in many instances, the epiglottis will be more or less pendent,—as may be ascertained by a laryngoscopic examination. In all laryngeal diseases, it is the duty of the practitioner to make a careful and thorough exploration of the chest, in order to determine the presence or absence of lung disease.

In these cases, the symptoms are, as a general rule, much more severe than when either disease exists alone, and also progress with more rapidity. There will be a distressing, more or less constant cough, pain in the larynx, difficulty of breathing, purulent expectoration, emaciation, hectic fever, night sweats, etc. Elongation and relaxation of the uvula is often present, augmenting the irritation at the epiglottic region, and causing increased cough, tickling sensation in the throat, and nausea. The fauces are also apt to be in a relaxed condition, and the tonsils lessened in size and covered with follicular enlargements. A change in the voice from a harsh roughness to an almost inaudible whisper may exist when the ulcer-

ation has attacked the vocal cords, as well as when there is ossification of the cartilages present. The other symptoms of laryngeal disease, as well as of phthisis will also be present in a greater or less degree. This complication of diseased organs will frequently exhaust the patient, who will perish before his lung disease has reached its terminal stage.

In many instances, instead of consumption, the laryngeal or pharyngo-laryngeal disease will be complicated with chronic bronchitis, in which case, in addition to the usual laryngeal symptoms, there will be cough of a loud ringing character, and a free expectoration of a clear and viscid mucus, or, of muco-purulent matter.

In either instance, the larynx should be treated by the appropriate means, for, although we may not always expect to effect a cure of the consumption, yet we may greatly relieve the distressing cough and other harassing symptoms, and, by thus checking irritation and even curing the laryngeal ulceration, prolong the patient's life and render him comfortable. The bronchial complication is generally much more remediable than that of the lung.

In conjunction with the remedies administered for the pulmonary, or the bronchial complication, the treatment will be the same as already advised for the several features which the laryngeal disease may present. Using topical applications to the congested and ulcerated parts; inhalations of soothing and astringent fluids, or of pulverized medicated fluids; external counter-irritation to the sides of the neck, and top of the sternum, as well as along the cervical vertebræ; a very excellent counter-irritant in these tuberculous cases is, a strong ethereal solution of Iodine,—it is apt to cause extreme pain and irritation, but generally has a very favorable effect; applications to the interior of the larynx of Olive Oil, Oil of Sweet Almond, Cod Liver Oil, Borax dissolved in Glycerin, or a solution of two, three or four drachms of Bromide of Ammonium in a fluidounce of Glycerin, which may be applied every day or two, by means of a curved brush, in order to allay irritation; and, in some cases, relief will be obtained by inhaling a small quantity of Chloroform, but not to produce anæsthesia. The uvula should be excised if it be elongated, and the patient should not be allowed to use his voice.—Slightly stimulating expectorants will frequently prove serviceable in producing warmth and free expectoration,—as, Senega, Colt's-foot, Bloodroot, Canada Balsam, Gum Ammoniac, etc.,—and, in the bronchial complication, Lobelia, Tolu, Queen of the Meadow, Stillingia, Elecampane, Hydrochlorate of Ammonia, etc.

ULCERATION AND DESTRUCTION OF THE CARTILAGES OF THE WINDPIPE.

When chronic laryngitis, having reached the stage of ulceration, is allowed to progress without treatment, or, is not benefited by the treatment pursued, the ulcers gradually extend in depth and involve the muscles, ligaments, and cartilages. The epiglottis, the arytenoid, cricoid and thyroid cartilages, the vocal cords, and the tracheal rings, are especially exposed to the inroads of this morbid action. The cartilaginous attachments being gradually destroyed by the ulceration, the cartilage implicated, usually the arytenoid, becomes partially displaced giving rise to difficult breathing, frequently of an alarming and spasmodic character. During the stage of displacement, alarming symptoms of suffocation are present, which frequently produce death before any assistance can be rendered. This suffocative respiration is generally due to a loose, displaced portion of cartilage, and, if this can not be promptly removed with slender curved forceps assisted by the laryngoscope, the only chance left for the patient will be tracheotomy, which should be performed immediately. Sooner or later the cartilage itself becomes destroyed, necrosed, and is ultimately expelled, and which affords relief for a time.

The more usual *symptoms* are laryngeal pain and soreness; a wheezing, or noisy and stridulous breathing; hoarseness; oppressed breathing; more or less difficulty of swallowing; on attempting to swallow, a regurgitation of fluids, and sometimes of solid food, through the nostrils; a hacking, distressing cough, frequently of a metallic, barking, or crashing character; a purulent expectoration, fetid, and sometimes streaked with blood; offensive breath, which is an indication of death of the cartilages with purulent accumulations around them; voice wheezy, whispering, or gone; often a violent cough, followed by a tough ropy discharge; a sensation of being choked up with phlegm; repeated attacks of spasm of the glottis, from the irritation produced by the necrosed cartilage, or, frequently following the act of deglutition in which the epiglottis and loosened arytenoid cartilages are brought into irritative contact with each other; more or less ulceration and destruction of the uvula, and other soft tissues of the throat; disengagement at various periods of one or several pieces of necrosed cartilage, generally during cough; paleness; emaciation; night sweats; pulse feeble and small, rapid, or natural; and death from exhaustion, or from suffocation occasioned by a partially detached cartilage, or by

closure of the glottis from œdema or spasm. Although all of these symptoms will not be present in any one case, yet, as a general rule, several of them will be noticed.

The results of a *laryngoscopic examination* will vary according to the seat of the disease, and the condition of the parts; there may be a relaxed and congested condition of the faucial and laryngeal mucous membrane; an abnormal redness, sometimes of a purplish hue; redness of the epiglottis; enlargement of the follicles, at the base of the tongue; uvula gone; epiglottis destroyed; aryteno-epiglottidean folds more or less destroyed or deformed; arytenoid cartilages gone; vocal cords gone, either one or both of them, or ulcerated; ventricular cords more or less ulcerated or destroyed; and various other appearances indicative of the extent of the ravages of the ulceration.

The *prognosis* is always unfavorable, depending upon the extent of destruction of the parts, and their location. In some cases, great relief may be afforded; and, in the milder forms of the malady, life may be prolonged several years.—A very imperfect cure can only be hoped for, when irritation has subsided, from an expulsion of the whole of the diseased cartilage, leaving the larynx free for the passage of air; this, however, rarely occurs, owing to the disproportion between the size of the cartilages, and that of the rima glottidis. If the disease is confined to the arytenoid cartilages, as sometimes occurs, they may be expelled by coughing, and the symptoms of “laryngeal phthisis,” as the disease under consideration is frequently termed, may cease; but, in cases of this nature, we have more to dread from œdema of the glottis, or from such an inflamed and tumefied condition of the lips of the glottis, as may destroy life by suffocation. The great danger is from a sudden closure of the glottis. The disease is frequently complicated with tubercular phthisis, which the practitioner should in all cases endeavor to ascertain, by a careful and well-conducted examination of the chest.—In the advanced stage of cartilaginous disease, local applications are useless, and internal remedies are of no avail whatever.

Pathological examinations also vary; in addition to a confirmation of the diseased appearances detected by the laryngoscope, the thyroid cartilage may be found perforated by one or more ulcers, or necrosed, denuded of its perichondrium, and enveloped in purulent matter, or, one wing alone may be diseased, or, portions of it may have exfoliated. The arytenoid and cricoid cartilages are more commonly diseased; the former may be denuded anteriorly, may be mortified, or entirely gone; the latter may have its anterior part

gone by mortification, together with the upper tracheal rings; or, it may be destroyed posteriorly by an abscess, or, it may be necrosed, displaced, or, more or less of it be absent. Denudation and destruction of the ligaments are often present; suppurative perichondritis, from inflammation commencing in the cartilaginous structures, is sometimes present, giving rise to abscesses, which may discharge their contents in various directions. Ulcerations may be observed in various parts of the larynx and trachea; and, sometimes, especially in long-standing cases, the cartilages will become wholly or partially ossified. The epiglottis may be enlarged, thickened, swollen, ulcerated, contracted and shrivelled, or destroyed to a greater or less extent. The above are some of the principal effects of the disease, observed in post-mortem investigations.

The *treatment* in this malady, though occasionally followed by a cure, is in nearly all cases of a palliative character, the principal object being to relieve severe symptoms and smooth the patient's passage to the grave. In many respects it will resemble that named for Chronic Laryngitis, adopting the same constitutional and hygienical measures. Absolute rest of the vocal organs is required, and cough must be controlled or alleviated by the proper remedies. Swallowing must be rendered as easy as possible by the adoption of a diet composed of jellies, strong animal broths, and other soft or fluid and nutritious preparations. Where there is much difficulty or soreness in swallowing, or where, from destruction of the epiglottis, there is an inability to swallow liquids, the patient may be fed through a tube passed into the œsophagus. Ulcerations require the same treatment as named under Chronic Laryngitis. The Belladonna Plaster, Terebinthinate Liniments, fomentations of Lobelia and Stramonium Leaves, may be applied to the neck to relieve irritation, and spasm of the glottis; and for the latter symptom, Gelseminum or Lobelia, may be administered internally at the same time, when the danger is not so imminent as to require surgical measures. Dr. Gibb advises a fistulous opening to be made into the trachea, in order to relieve the dyspnœa, and through which, to remove necrosed portions of laryngeal cartilage, as well as to make the necessary local applications to the diseased surfaces,—this holds out a chance for the laryngeal mischief to improve, and in favorable cases to heal up and get well. It should not be left to the last moment, but should be performed as soon as the symptoms indicate necrosis to be present,—and, after immediate danger is overcome by cutting an orifice in the trachea, the thyroid cartilage must be laid open through one of its wings, so that the pent-up dead portion of cartilage can be removed. Then,

if the disease is checked by the local applications made through this wound, it can be closed at a future period by a plastic operation, the fistula lower down being permitted to remain open for the purposes of breathing, as long as may be required.

Syphilitic Disease of the Larynx occurs in broken-down constitutions from the syphilitic dyscrasia, and almost always among those who have taken mercury. The laryngeal disease is generally an extension of the disease from the pharynx and fauces, and is usually associated with secondary eruptions, emaciation, debility, and a peculiar wan appearance. The *symptoms* will vary according to the character and extent of the local affection. Sometimes there will be a rapidly spreading ulceration, giving rise to supraglottic œdema, followed by sudden death. In most instances, however, the affection assumes a more chronic condition, giving rise to one or more of the symptoms of chronic laryngeal disease, as, partial or complete aphonia, or a hoarse stridor in speaking, suffocative cough, expectoration of pus and blood, pain in some particular part, frequently difficulty in swallowing, and, sometimes, abscess and fatal dyspnoea from its pressure inward, simulating œdema. In nearly all instances there is some amount of supraglottic œdema, giving rise to a corresponding intensity of dyspnoea. Both the history and the appearance of the patient will indicate the true nature of the laryngeal affection.

Besides the more or less extensive ulceration that may be observed in the fauces, pharynx, tonsils, uvula, and soft palate, and as far upward in the pharyngo-nasal recess as may be, by the rhinoscope, the *laryngeal mirror* will reveal, according to the character of the local malady in the larynx, more or less intense redness of a greater or less portion of the larynx, trachea, and vocal cords; deep red patches in the larynx; an œdematous condition of the ventricular cords, or a thickening of the mucous membrane over the arytenoid cartilages, and at the side of the larynx, in the situation of the ventricular cords; projections of portions of the soft structure of the interior of the larynx in the form of little folds or projections simulating growths; ulceration of various parts, as, of one or both vocal cords, of the aryteno-epiglottidean folds, of the posterior surface of the larynx, of the trachea, of the epiglottis on its lingual surface, its tip, its base, or in the hollow on either side of the frænum of the epiglottis, etc.; more or less œdema of some of the parts above the glottis, etc. Generally the syphilitic ulcers, have a sloughy base, are larger, more extensive, deeper, and irregular,

while the tuberculous are smaller, rounder, more superficial, and scattered over the superficial structures. Some of the appearances referred to under Chronic Laryngitis, Ulceration and Destruction of the Cartilages, Ulcers of the Epiglottis, etc., may likewise be observed.

The *treatment* will consist of constitutional measures for the removal of the syphilitic affection, conjoined with local applications to the morbid surfaces, growths, ulcers, etc., of Nitric Acid, solution of Nitrate of Silver, Chloride of Zinc, Chloride of Gold and Soda, or, a solution of Chloride of Zinc eight grains, Chloride of Gold and Soda four grains, Water one fluidounce; to which three or four grains of Muriate of Morphia may be added if there is much soreness or irritation. To be applied by means of the laryngeal mirror, and instruments heretofore mentioned. Pulverized fluid, or the spray of Nitrate of Silver solution, or of solution of some other preparations heretofore named for the treatment of laryngeal diseases, ulceration, etc., will also be found exceedingly beneficial in syphilitic laryngeal disease.—Should supra-glottic œdema be present, threatening suffocation, *tracheotomy*, not laryngotomy, should be resorted to, because, ulcers frequently exist in the inferior part of the larynx, and a chance is then held out for a better recovery with some voice. If the amount of swelling and obstruction in the larynx, as seen by the laryngoscope, is such that the most successful medicinal treatment could not be expected to remove it for at least several days, speedy suffocation being threatened from narrowing of the glottis, we should always resort to tracheotomy before the lungs have become gorged to such an extent as to render the operation useless.

The ulcers in the fauces, pharynx, pharyngo-nasal recess, tonsils, etc., should also be treated daily by similar local applications, being aided in the operation by the rhinoscope when required. I prefer Nitric Acid to any other agent for application to these ulcers.

DISEASES OF THE EPIGLOTTIS.

In a passive state, when the tongue is protruded forward, the epiglottis should be naturally in an erect or vertical position; but it is not always found in this position, being frequently situated more obliquely, in various degrees from that of its normal standard to an almost horizontal position, and this too in persons presenting no symptoms of disease. This depression backward or PENDING OF THE EPIGLOTTIS, is occasionally congenital, when it becomes a matter of considerable danger to children suf-

fering from any of the diseases of childhood involving the throat, as, croup, diphtheria, scarlatinal angina, etc. According to Dr. Gibb, about eleven per cent. of mankind, including adults and children, males and females, have not a vertical or erect epiglottis; and, perhaps, this per centage may eventually be found still greater.—It is generally the result of frequent catarrhal attacks, sore throat, or follicular disease, which renders the contractile power of the glosso-epiglottic ligament more or less enfeebled; and sometimes likewise gives rise to a spasmodic action of the aryteno-epiglottic folds, which occasion a persistent depression backward of the epiglottis. This condition may also be associated with congestion of the cartilage, and the patient's voice becomes thick and guttural, with more or less dyspnœa, a sensation as if some foreign body were at the root of the tongue, efforts to clear the glottis, suffocative attacks, irritation and burning sensation in the throat, feebleness of voice, tickling sensations in the throat, cough, and various odd sensations.

The application of a probang to the lingual surface of a pendent epiglottis is fraught with danger, and no practitioner is free from censure who attempts such applications without having first made himself acquainted with the position of this cartilage by a laryngoscopic examination. For, if the sponge come in contact with this surface of the epiglottis, it must force it farther downward, and for the time being close up the glottis.

The *laryngoscope* will detect the depressed epiglottis, which may be congested, ulcerated, curved toward one side, or doubled up laterally like a scroll, stiff, thickened, etc. Catarrhal or follicular disease of the fauces may also be observed; and, if the epiglottis can be raised by sudden forcible expiratory efforts, more or less laryngeal disease may also be revealed—but it is not in all cases where such efforts will enable the observer to get a view of the larynx.

The *treatment* will vary according to the condition of the epiglottis; if much irritation be present, soothing and anodyne gargles may be used, as, an infusion of Hops, Poppy Leaves, Mullien Leaves, Peach Leaves, etc.; and, in many cases, the addition of one-third or one-half part of Vinegar to the infusion will be advantageous,—or, the gargle may be composed of Vinegar and Water a gill, to which a teaspoonful of Salt may be added, or the same amount of Laudanum. When the irritation is not very severe, tonic and astringent gargles may be used, as, of Golden Seal and Geranium; Witch Hazel and Golden Seal; Blue Cohosh and Golden Seal Bayberry, Marsh Rosemary, Blackberry Root, etc. When there

is a lax, enfeebled condition of the affected parts, gentle stimulants may be added to the gargles, as, infusions or decoctions of Prickly-ash Bark, Virginia Snakeroot, Capsicum, Colt's-foot, Sage, Spirits of Camphor, etc.

The epiglottis should be frequently showered with weak solutions of Perchloride of Iron, Sulphate of Zinc, Nitrate of Silver, ten, twenty, or forty grains to the fluidounce, or, Sulphate of Quinia, or other tonics, etc.; and in very obstinate cases, a drop or two of a dilute solution of Nitrate of Strychnia in Glycerin may be dropped upon the inferior part of the lingual surface of the epiglottis, by means of a graduated laryngeal syringe, and be repeated once or twice a day.

Counter-irritants along the sides of the neck, and on each side of the cervical vertebræ, will frequently prove serviceable as auxiliary means, and, in all instances, any accompanying pharyngeal or laryngeal disease must be treated at the same time; the latter, however, only when the cartilage can be so elevated as to allow the practitioner an opportunity of inspecting it, and applying remedies by the aid of the laryngeal mirror.—Constitutional measures will not be necessary in simple pendency of the epiglottis, unless there be extreme debility, or some syphilitic taint, struma, etc., present. .

Ulceration of the Epiglottis may exist independently of any disease of the larynx, but more frequently associated with it; it is the result of inflammation, or may be caused by an extension of pharyngeal or laryngeal disease. The *symptoms* are, hoarseness, soreness, pain, especially in swallowing, and which is located under the cornua of the hyoid bone, irritative cough, and expectoration more or less tinged with blood and increased after eating. Deglutition is very difficult, and on attempting to swallow fluids, they will be frequently ejected through the nostrils; this is especially the case when the epiglottis is partly or wholly destroyed.

In making a *laryngoscopic examination*, care should be taken to thoroughly pull the tongue in a forward direction, when the ulcerations may be seen. Any part of the epiglottis may be ulcerated, but the more frequent parts are the borders, and that portion of it situated close to the base of the tongue. The ulcers are very apt to have ragged edges, and to give an uneven and notched appearance to the margin of the cartilage. If the ulcers are syphilitic, they will have a sloughy base, and are more commonly seated on the lingual surface of the epiglottis; though all ulcers at this loca-

tion must not be deemed syphilitic. When the ulcers are on the laryngeal surface of the epiglottis, this cartilage becomes somewhat flattened instead of crescentic; also enlarged, and thickened from submucous infiltration, and the ulcerations spreading to its border, give to it a serrated appearance. In some ulcerations, the epiglottis will be nearly erect, or pendent, incurvated, or rolled up like a scroll. It must be remembered that, not unfrequently, ulceration of the larynx and epiglottis is associated with, or dependent upon tubercular consumption, in which instances, the symptoms are usually of more aggravated character, and run their course more rapidly; the ulcers, in such cases, differ from those resulting from idiopathic laryngeal disease, in being of a tuberculous character. Bronchitis is also often met with as a complication of the throat disease.

Sometimes, instead of ulcers, *erosions* will be observed upon the border or center of the epiglottis, the result of irritation from follicular disease, or from tubercular phthisis. These erosions seldom, if ever give rise to ulcerations.—Occasionally, the free portion of the epiglottis will be found more or less destroyed, and when this is the case, deglutition will be difficult or wholly impossible.

The *treatment* of ulcerated epiglottis consists in the topical application of strong solution of Nitrate of Silver, of concentrated Nitric Acid on a soft piece of wood, or of Perchloride of Iron, etc., being careful to have the solution used come in contact with every portion of the surface of the ulcer. In strumous patients, after healthy action has commenced in the affected parts, by the use of the above applications, the subsequent treatment may consist in applications of Bromide of Ammonium ten or twenty grains to half a fluidounce of Glycerin; or, Iodine, Iodide of Potassium, each, one scruple, Glycerin one fluidounce; mix. Or, of Iodide of Silver, Iodide of Ammonium, each, five or ten grains to a fluidounce of Water. Re-applying the previous agents occasionally, or whenever the healing process appears retarded. *Erosions* may be removed by a strong solution of Nitrate of Silver applied to the whole cartilage; by the application of the above-named mixture of Iodine and Glycerin; and, in many instances, by a solution of Chloride and Gold and Soda two grains, Hydrochlorate of Ammonia four grains, in Water one fluidounce. These various agents are to be applied by means of a soft brush, or curved syringe, and not by means of a sponge; except the Nitric Acid, which must be applied as heretofore named, page 569.

Soothing and astringent gargles should not be neglected; those named under the treatment of Pendent Epiglottis will be found use-

ful.—If the epiglottis be partially or completely destroyed, of course there can be no hope of restoring it, yet with a view to relieve the patient and perhaps to prolong his life, measures should be adopted to remove any abnormal conditions of the throat, larynx, etc., that may be found remaining; and, indeed, this will be necessary at any time during the ulceration, as soon as the various parts of the larynx can be observed, and remedies be applied by means of the laryngoscope. In all instances, such constitutional treatment should be prescribed as the condition of the patient demands; and the hygienic means should be in accordance with those named under Follicular Pharyngo-laryngitis, and Chronic Laryngitis.

Mucous cysts and vesicles containing fluid may be observed upon the laryngeal surface of the epiglottis, requiring to be opened by incision. Sometimes various deformities of this cartilage will be noticed, for which nothing can be done, as, a fissure in the median line, a circular aperture through it, or, it may be twisted or doubled, laterally or backward, or may be elongated.

APHONIA.

Aphonia is a term applied to a complete loss of the voice, including any modifications or alterations of it that are not natural. It is divided into functional aphonia, and organic aphonia.

FUNCTIONAL APHONIA is always associated with either general or local impaired nervous power, or deranged innervation, without any manifest lesion of structure; it may be due to various circumstances, among which may be named—*emotional causes*—as excessive and sudden joy, grief, anger, or fright, etc., or whatever mental emotion will occasion a strong shock to the nervous system, and especially to the laryngeal nerves; and the loss of voice may occur suddenly or within a short time after the mental excitement, continuing for weeks, months, or even years, and then suddenly become restored to its normal condition, without any apparent cause.

Impaired innervation from constitutional influences, which give rise frequently to a very obstinate aphonia. These influences originate from enfeebled conditions of the system, which impair the nervous energy of the larynx, either by direct or reflex action. Profuse hemorrhages, anemia, chlorosis, leucocythemia, leucorrhœa, dysmenorrhœa, and derangements of the digestive organs, may all give rise to aphonia; so may rheumatism; and, in some instances,

a greater or less suppression or modification of the voice will be met with at the period of menstrual cessation.

Hysteria is frequently a cause of aphonia, but not to such an extent as was supposed in former years. It occurs chiefly among delicate, nervous, or hysterical females, at some time during their catamenial existence, and may be known by being associated with uterine derangements, and other hysterical symptoms. The aphonia usually manifests itself suddenly, and may, after a longer or shorter time, return as suddenly without any treatment, or, it may momentarily return at regular or irregular periods, for a number of times previous to its spontaneous disappearance. Hysterical aphonia has been known to continue for three or four years before it became permanently removed. Not unfrequently the natural voice returns momentarily when the patient is under the influence of strong moral excitement. This form of the disease is sometimes met with among males of a highly nervous and debilitated condition of the system, sedentary persons, and those who are frequently called upon to speak in public in an elevated tone of voice.

Certain local influences may also impair the nervous energy of the vocal chords, producing a more or less complete paralysis accompanied by aphonia, as, overexertion of the voice in singing, reading, public speaking, etc.; congestion of the vessels of the laryngeal mucous membrane, neuralgia of the throat; local paralysis from any cause, especially as a sequel to the exanthematous diseases, diphtheria, hooping cough, etc.

Compression of the pneumogastric nerves, or of their branches, will also give rise to aphonia, curable only by the removal of its cause. This cause may be, bronchocele, glandular enlargements, aneurisms, or other morbid growths in the immediate vicinity of the larynx or trachea. Irritation of the branches of the nerves will sometimes cause a more or less complete loss of voice.—Aphonia is occasionally the result of certain *poisons* which have been introduced into the system, producing a nervous exhaustion or paralysis, as, arsenic, antimony, mercury, and, especially, lead. This form of aphonia is generally associated with the effects of the poison in other parts of the system; and, when occasioned by lead, the characteristic blue line will be observed on the margins of the gums.—*Exhausting diseases*, as, cholera, are likewise frequently accompanied by laryngeal difficulties terminating in aphonia.

The character of the aphonia, or the change of voice in all these instances will differ according to whether one or both of the vocal cords are affected, and whether the loss of nervous power is complete or incomplete. There may be more or less considerable

hoarseness, a nasal timbre of the voice, whispering, or complete aphonia.

A *laryngoscopic examination* will discover, in most instances, a normal color of the vocal cords; sometimes they will be observed quite pale or white; and, occasionally, they will present a pinkish redness; or they may be covered with disseminated red spots upon their surfaces; or, one or more red lines (strongly distended veins), may be seen running across them. The mobility of the cords may be observed to vary; in some instances, there will be no movements whatever, in others the movements are imperfect or insufficient, so that the cords do not approach the median line in an equal manner; thus, they may not meet each other, leaving a larger or smaller space between them, according to the degree of paralysis present, or, they may slightly approximate anteriorly, but much less so posteriorly, where they leave quite a space for air to rush through, or, they may approximate more closely at their extremities and less so at their centers, forming thin arcs of a circle, or, although they meet each other properly, yet a slight aperture is formed posteriorly, which allows the air to pass outwardly. Frequently, there will be an abnormal condition in the power of tension in one or both cords, which is generally due to a more or less paralytic condition of the three constrictor muscular groups of the glottis, as, the lateral crico-arytenoid, the arytenoid, and the thyro-arytenoid muscles. Sometimes, but not always, there may be a congestion of the larynx or trachea, or, of both.

The *prognosis* of functional aphonia, as a general rule, is favorable. Though cases will sometimes be met with which obstinately resist all our remedial measures, the aphonia being permanent and incurable; these unyielding cases are due to several causes; as, a constitutional defect in impaired innervation,—some minute or molecular change of the muscular fibers, of which we are at present not cognizant, the result of overstraining of the voice, or of some equally injurious action,—long-standing emotional aphonia with resulting atrophy;—or, mechanical pressure on the nerves.

The *treatment* of functional aphonia, consists principally in the direct application of agents to the vocal cords and surrounding parts, for the purpose of stimulating nervous force, and which agents, in all instances, are applied with the aid of the laryngeal mirror. Thus, by means of the laryngeal shower-syringe or fluid-pulverizer, the parts may be showered every one, two, or three days with a solution of Nitrate of Silver twenty grains to the fluid-ounce; or, other tonic, as, Sulphate of Copper, Sulphate of Zinc, Golden Seal and Geranium, etc. In some instances, especially

when the aphonia is recent, a solution of Nux Vomica or Strychnia carefully showered upon the cords will restore muscular contraction and closure of the glottis, with a return of voice. The above various solutions may be formed of Water, Glycerin, or equal parts of each; and their strength will vary according to their influence, commencing with weak solutions at first. Strychnia solutions should not contain over two grains of the alkaloid to the fluid-ounce, of which not more than from fifteen to twenty-five minims should be used at a time, by means of a graduated laryngeal syringe.—Direct Faradization of the vocal cords and arytenoid cartilages has cured many obstinate and long-standing cases, but it also frequently fails; it is applied by means of an instrument termed the “laryngeal galvanizer,” or “electropole.” Currents of moderate power only should be employed. For the mode of application the reader is referred to “Althaus on Medical Electricity,” to “Medical Uses of Electricity,” by Garratt, to “Gibbs on the Throat and Windpipe,” and to the works on Laryngeal Diseases, by Elsberg, and by Semeleder.—Stimulating vapors, by inhalation, frequently produce surprising effects, as, the vapor of Oil of Turpentine, Tobacco smoke, vapor of Ammonia, or of Iodine, etc.; but great care should be taken to avoid causing inflammation or too active a degree of irritation.

External applications will also be found serviceable; counter-irritation may be made alternately to the front of the neck, to the sides, and along the course of the cervical vertebræ, by means of the Compound Tincture of Camphor, Compound Liniment of Stillingia, Compound Liniment of Oil of Amber, Croton Oil Liniment; and, in obstinate, long-standing cases, the Compound Tar Plaster may be used. In a few instances I have derived much benefit from an external application of the following preparation, used daily or every other day: Take of Strychnia twenty grains, Veratria forty grains, Oleic Acid four fluidrachms; mix, dissolve the alkaloids, and then add Olive Oil, or Simple Cerate fifteen and a half drachms. Use a small portion of this at a time, rubbing it well into the neck and on each side of the cervical vertebræ, and being extremely careful not to apply it where the skin is scratched or abraded, etc. This will likewise be found a very valuable application in laryngeal spasmodic affections of a suffocative character, or occasioning severe dyspnœa.—When the aphonia is due to certain local influences, a strong ethereal solution of Iodine may be applied to the external throat, with advantage in many cases; it is a powerful counter-irritant, and frequently exerts a more decidedly beneficial influence than other agents of this kind.

Internally, tonics are required; as, the Citrate of Iron and Quinia, Citrate of Iron and Strychnia, Citrate of Iron and Quinia with Strychnia, in conjunction with Alcoholic Extract of Aletris, Black Cohosh, or Blue Cohosh, Oleo-resin of Ptelea, etc. Any renal, hepatic, gastric, or other malady, that may be present, will require suitable treatment, as well as any peculiarity of the constitution, debility, scrofula, syphilis, erysipelas, etc. In the hysterical female, there is almost always some menstrual derangement, which will require especial attention; and the restoration of the normal menstrual function will be followed by a return of the voice. The local measures, referred to above, may also be pursued. Frequently, in aphonia due to hysteria, the voice will return as suddenly as it was lost, and without any appearance of wasting debility, or exhaustion. When the aphonia is due to lead in the system, Iodide of Potassium, of Ammonium, or of Soda, with some preparation of Strychnia, internally.—Faradization of the vocal cords,—and plasters of Sulphur, or of Sulphuret of Potassa to the anterior part of the neck, will be found advantageous.—Gentle exercise, in the open air when possible, nutritious diet, and attentions to the bowels, skin, and kidneys should never be overlooked.

Organic Aphonia may likewise be due to various causes, among the most common of which are the following: *Acute or chronic inflammation* of the mucous membrane of the larynx, epiglottitis, and vocal cords, and which may be associated with catarrhal inflammation or bronchitis. In the acute inflammatory attacks, the loss of voice is preceded by hoarseness, and the voice may disappear gradually or quickly, being reduced to a mere whisper, or wholly absent. Pain or soreness is experienced in the larynx, and a *laryngoscopic* examination will find a vivid redness of the vocal cords, especially upon their free margins, and, in some cases, a strongly-distended vein running parallel with the free inner edges of the cords may be seen; the cords may, in some instances, appear bloody, with croupy cough and dyspnoea. The cords are usually more or less tumefied. The larynx will also be observed more or less congested and red. When the aphonia is due to chronic catarrhal inflammation, the vocal cords are not so intensely red as in the acute attack, the larynx is more congested, however, and its lining membrane somewhat swollen and relaxed. Or, there may be only a slight discoloration of the vocal cords, or, they may retain their normal color. The uvula is apt to be relaxed and elongated, and the pharynx and posterior nares may

present a congested appearance. The chronic inflammation, if not removed at an early period, is very liable to effect several changes in the parts, which I will now proceed to consider.

Induration and thickening of the vocal cords is one of the results of chronic inflammation, and is more frequently observed among females. The *laryngeal mirror* will reveal a dark red color of the cords, which have a rounded and elevated appearance, owing to depositions beneath the mucous membrane, or to its thickening. This thickening may also be due to a hypertrophied state of the proper tissue of the cords, or to interstitial deposits. In either case, the vocal cords become somewhat indurated and rigid, with a constricted condition of the orifice of the glottis. In instances of hypertrophy or interstitial deposition, the structures below the glottis are apt to become affected, and foreign growths frequently protrude from some portion of the diseased cords.

Œdema is another result of chronic inflammation of the vocal cords, and which will be more especially referred to hereafter.—Supra-glottic œdema of the vocal cords may be associated with an œdematous enlargement of the ventricular, which latter may become so extensive as to occasion pain and soreness even upon attempting to whisper, and will frequently prevent the true cords from being observed in the laryngeal mirror. It is very apt to be present among patients subject to gout, rheumatism, albuminaria, syphilis, etc.—Sub-glottic œdema exists when there is an effusion of lymph beneath the membrane, and directly involving the cords, so as to wholly impede their action. The larynx has its diameter lessened, the 'cricoid' cavity becomes nearly filled up by submucous indurated tissue (organized lymph), reducing the voice to a hissing or feeble whisper.—Aphonia may also result from œdema of the glottis, or of the aryteno-epiglottic folds.

Ulceration of the vocal cords is another consequence of chronic inflammation, inducing aphonia, and is much more frequently met with among males than females. If the mucous membrane of one of the vocal cords only is affected, the voice is rendered rough and hoarse, but some degree of vocal resonance remains; if the investing membrane of both vocal cords ulcerates, the voice loses its power and becomes little more than a rough whisper; and if, not merely the mucous membrane, but the proper tissue of the vocal cords are injured or destroyed by the extension of the ulceration, the state of the aphonia is complete, no proper vocal sound is distinguishable, and a whisper, which is simply an articulation of the ordinary respiration, alone remains. The voice is very liable to become more or less altered by ulcers in other parts of the larynx, speaking being

accompanied with a sense of pain, and followed by more or less uneasiness or fatigue. Aphonia may follow ulceration of the fossæ at the roots of the tongue, and on the sides of the aryteno-epiglottic folds. If the ulceration be seated on the posterior wall of the larynx, or between the arytenoid cartilages, vomiting is apt to occur. Sometimes, when the vocal cords are denuded by the ulceration the only alteration observed in the voice, will be its rough and hoarse character.

The *treatment* of organic aphonia from inflammation, induration and thickening, or ulceration, is by local applications of aqueous or glycerine solutions of Nitrate of Silver to the cords, every day or every other day, by means of a laryngeal syringe, a curved camel's hair pencil, or, when it can be accomplished, by inhalation of the dust of the powdered nitrate. The solution may vary from forty to eighty grains of the silver salt to the fluidounce; the weaker solution of the above being more usually employed. Other solutions may sometimes be advantageously employed, as, of Sulphate of Copper, Nitrate of Copper, Aluminated Sulphate of Copper, Sulphate of Zinc, Sulphate of Zinc and Alum, Sulphate of Zinc and Morphia, Perchloride of Iron, Persulphate of Iron, Permanganate of Potassa, Iodide of Silver and Potassium, etc. All of these agents have been used with benefit, but great care should be taken not to have the strength of the solution so great as to destroy the tissues with which they come in contact. In some instances of induration and thickening, or ulceration, a solution of Chloride of Gold and Soda two to four grains to the fluidounce, with four to eight grains of Hydrochlorate of Ammonia, will prove extremely efficacious. And in instances where the application can be made by means of a soft stick as heretofore named, Nitric, Hydrochloric, or Chromic Acid may be touched upon the ulcerated or indurated cords with great advantage. The chromic acid will require a platinum sponge or filamentous asbestos extremity to the porte-caustic, which should be large enough to hold only part of a drop.—In connection with these applications, it will always prove highly advantageous to make counter-irritation externally, upon the neck, the sides of the neck, and along the cervical vertebræ, by rubefaction, pustulation, or suppuration.—Inhalations of warm vapors will frequently afford benefit, as, of gum Ammoniac, Turpentine, Camphor, Iodine, Creosote, Benzoic Acid, Extract of Stramonium, Opium, Aconite, or Arnica, the particular agent employed depending upon the irritation, cough, degree of nervous debility, etc., present.

In addition to attentions to the condition of the skin, bowels, and kidneys, and other necessary hygienic measures, internal remedies

will be required to overcome active inflammatory symptoms, when present; or, in the absence of these active symptoms, alteratives will be demanded, as, Compound Syrup of Stillingia, or one of the several preparations heretofore named of the Iodides and Bromides. A persistent employment of the means recommended will frequently effect a cure in four or six weeks of an aphonia that has been in existence for several years; though it must not be expected to make such rapid cures in all instances. In many persons, the loss of voice will be irremediable; ulceration of the vocal cords may effect such destruction of them as to wholly prevent a return of the voice, or, else, to render it more or less modified from its usual characters when existing during health. But if only the mucous membrane of the cords be ulcerated, a perfect cure may be effected.—It is very rarely the case that œdema can be remedied in time by local medications; the proper course to pursue will be named hereafter, under Œdema of the Larynx.

Foreign growths upon the vocal cords, or, in their immediate vicinity, may also be a cause of organic aphonia. These morbid growths are of various characters, presenting themselves, as, warty excrescences, or growths resembling a cauliflower, papillary vegetations, foliated epithelial growths, etc.; cartilaginous and other tumors; polypi, etc. According to Dr. Gibb, to whose work on Laryngeal Diseases I am largely indebted for the history and management of these maladies, laryngeal tumors are seated mostly above and below the *origin* of the true vocal cords, being larger and more disseminated when above, and smaller and more compact when below. The root of the epiglottis above the vocal cords, and the sub-glottic space anteriorly below the cords, are the points at which these growths are more commonly observed; the next points in frequency are, the anterior free borders of the vocal cords, and progressively backward upon their surface and border; next, the inner surface of the cricoid cartilage, below and between the arytenoid cartilages and vocal cords posteriorly; then, the ventricles of the larynx, the tumors growing from which point are apt to occasion imminent suffocation; and, rarely, they may spring from the false cords and the aryteno-epiglottic folds, as the result of catarrhal, syphilitic, or cancerous disease.—The epiglottis is more subject to those growths considered as syphilitic.—These foreign growths may vary in number from one to ten, and upward, and are of different sizes from that of a pin's head to that of a hazelnut; most generally they are about the size of a small pea.

Polypus is by far the most common species of tumor found in the larynx; it is variable both in form and structure, being roundish, irregularly-shaped, united in clusters, granular, lobulated, sessile or non-pediculated, but most generally pediculated. Its attachments, whether one or several, broad or slender, are seldom traversed by blood-vessels of any size. By some authors the warty or condylomatous growths are included among these polypi.—The *causes* of these morbid growths are not well understood; a persistent low grade of inflammation, a modification of local nutrition, frequent catarrhal attacks of the laryngeal membrane, and the syphilitic dyscrasia, have been considered exciting or predisposing causes, but there is no certainty in these views.—Several writers consider them to be a hypertrophied condition of the mucous membrane, especially involving its epithelial layer; the areolar tissue observed in it, belonging, as is generally known, to the structure of all the mucous membranes; and the fibrous tissue, more commonly observed at the base of these growths, forming, as it were, a transition between the true mucous polypus and the fibrous.

These growths are generally epithelial, being composed of all the elements of the mucous membrane united, but modified in character by the presence of fibrous or fibro-cellular tissue, the latter more especially in long-standing cases. The epithelial scales are of the squamous variety. In some rare instances, the tumors are cystic, fibro-plastic, fatty, and follicular; again, they may be only prolongations of the mucous membrane from a mucous follicle. Sometimes, they arise from an hypertrophied vocal cord whose structure has undergone some interstitial or molecular change.

The *symptoms* commonly present with these laryngeal vegetations, depend somewhat upon their location and size. There is a sensation of a foreign body in the larynx; stiffness or uneasiness in the acts of respiration and deglutition; more or less cough, which may be hoarse, or croupy, paroxysmal, or continuous, and with or without expectoration; more or less dyspnoea accompanying inspiration, or expiration, or both; the voice may be feeble, hoarse, or otherwise modified in its tone and character; paroxysms of suffocation, in one of which death ensues. Sometimes there may be pain or tenderness in the larynx, constricted feeling about the chest, tremulousness of the voice, etc. These symptoms will be found to vary considerably with different patients, owing to the seat, and extent of the growth, and, of themselves, are not positive indications of the existence of polypus.

Generally, in cases of this kind, the larynx, being quite capa

cious, can be easily examined by the *laryngoscope*, which will give a distinct view of the tumor or excrescence, especially when proceeding from the vocal cords, or between them in front, or behind. Those growths provided with a pedicle are more dangerous, but are also more easy to remove.

The *treatment* consists in removing the morbid excrescences either by topical applications, or, by an operation. The agents for their gradual removal are, Nitrate of Silver, Nitric Acid, Chromic Acid, Perchloride of Iron, Sulphate of Copper, Tannin, etc., with one of which, the growths may be touched daily or every other day, by means of the laryngeal porte-caustic, as heretofore explained; and which method is more applicable to those growths upon the upper surface of the vocal cords, no matter how small they may be, which have a firm base. And if this process fails, or if an immediate removal is absolutely necessary, the growths may be removed by the *laryngeal ecraseur*, and this will generally be found the best method in those cases where the attachment of the growth can be encircled by a loop of wire.

This is one of the most difficult operations undertaken for the removal of laryngeal maladies. The most expert operator will frequently fail to encircle the tumor at first, often requiring several attempts before he succeeds, and sometimes fatiguing the patient so much, that the operation has to be postponed for another sitting. When the operation is once decided upon, the parts should be accustomed to the presence of instruments, by repeated introductions of the laryngeal sound or bougie, which will also assist in overcoming the sensibility of the parts, and render the use of the laryngeal mirror and ecraseur more easy. Immediately before attempting the operation, the sensibility of the parts should be diminished by a few whiffs of Chloroform; by painting the fauces with a solution of Morphia in Chloroform, by means of a camel's hair pencil, also the interior of the larynx by a curved camel hair pencil; or, by the use of large doses of Bromide of Ammonium. The application of the mixture of chloroform and morphia to the inner walls of the larynx, is an unpleasant operation to the patient, but occasions no irritation, and it should be continued for a sufficient length of time, not to cause complete anæsthesia, but merely to diminish the sensibility of the parts and their resistance, from reflex action, to the presence of the instruments. This having been effected, the ecraseur is to be carefully introduced, and its wire noose be passed over the tumor so as to encircle the pedicle or base, when the growth may be removed in the ordinary manner. Should the tumor drop into the trachea, it

will occasion no trouble, being generally expectorated without any difficulty.—In some instances, the excrescences may be removed by small curved forceps, or minute vulsellum scissors; but, no matter what instrument is used, we should endeavor to remove the whole of the tumor at the one sitting, because an irritation may be produced by repeated operations at short intervals apart, which may degenerate into epithelioma and prove fatal. It is only in instances where the growth is large and disseminated, that it will sometimes be required to remove it in small fragments at several sittings. The operation will prove an exceedingly difficult one among children, requiring the presence of an assistant or two. Laryngeal polypus has been likewise removed by the galvanic cautery, applied by means of a laryngeal galvanizer or electropole.—After the removal of the polypus by instruments it will be well at a few subsequent sittings, at intervals of several days, to touch the point at which its base was attached, with a solution of Perchloride of Iron, of Chromic Acid, of Tannin, or of Strychnia, etc., in order to prevent its renewal. Internal remedies will be required in those cases connected with anemia, debility, scrofula, or syphilitic taint, as, Bromide of Iron, Bromide of Ammonium, Extract of Nux Vomica, etc., according to the character of the associated malady.—Sometimes there is a spontaneous detachment of these growths, which are then passed away, perhaps unnoticed, by expectoration.

Cerebral Disease is a very fertile cause of aphonia, from the resulting paralysis of the laryngeal nerves, and which condition may attend any one of the several maladies of the brain heretofore treated upon. If the paralysis be of long standing, the cords undergo a structural change, their color becomes altered, they appear narrow and wasted from atrophy, and present an irregularity of outline. The cure of the aphonia in these cases depends entirely upon that of the brain disease; should this be cured and the aphonia still remain, local applications to the larynx may be made for the purpose of arousing nervous and muscular action, and thus aid in restoring the voice.

Dr. Gibbs states that “if effusion into the substance of the brain be followed by hemiplegia, and aphonia, the arytenoid muscle and vocal cord of the side affected will be found paralyzed, in most instances. In these cases, the cerebral lesion generally affects but the one laryngeal nerve, combined with impaired power in some of the other nerves taking their origin from some neighbor-

ing part of the brain. In some severe instances the palsy is permanent, and speech is irrecoverably gone; there is incurable organic aphonia. Under these circumstances the vocal cords are seen to become atrophied, discolored, shrivelled, and sometimes effected with atheromatous degeneration."

In cases of hemiplegia, the movements of the aryteno-epiglottic fold of the affected side are sluggish, which interferes more or less with deglutition.—Paralysis of the velum palati, known by the nasal twang, the incapacity for suction, the regurgitation of fluids by the nostrils, and an insensibility to the contact of substances, frequently occurs as a sequel of diphtheria; and this may be associated with a relaxed condition of the vocal cords, and a partial or complete aphonia. The proper remedies internally, are, Citrate of Strychnia and Iron, and Iodide of Ammonium internally, with the local application of showers of a solution of Strychnia, or of Iodide of Silver, Iodide of Gold, Nitrate of Silver, Sulphate of Zinc, etc.

HOARSENESS, AND OTHER MODIFICATIONS OF THE VOICE.

Hoarseness or *Raucedo* may arise from the same causes that occasion aphonia; in the majority of instances, aphonia is preceded by hoarseness, and, in some cases, we may observe hoarseness and aphonia manifesting themselves alternately. A hoarseness of long standing is very liable to ultimately terminate in a permanent loss of voice.

Any condition that interferes with the normal action of the vocal cords will give rise to hoarseness; thus, it may be occasioned by a hyperæmic or congested condition of the larynx involving the mucous membrane of the cords; by a temporary congestion of the membrane covering the thyro-arytenoid muscles, as well as of the aryteno-epiglottidean folds, as, when substances come in contact with them in swallowing, or "go the wrong way,"—which foreign substances impair the action of the laryngeal muscles, by irritation, congestion, and the production of want of harmony and simultaneous action, and, there may also exist at the same time, congestion and tumefaction of the ventricular cords; by acute inflammation of the larynx and trachea; by laryngeal ulceration, and especially of one or both of the vocal cords, either with or without more or less loss of substance; by induration and thickening of the vocal cords, which limits their action, and contracts the diameters of the glottis; by morbid alterations of the proper

structure of the cords, which, in addition to the hoarseness, also render the voice harsh, cracked, and tremulous; by hypertrophy of the cartilages of Wrisberg, when these are present; by laryngeal œdema, whether above or below the glottis,—when below, the hoarseness is usually painful; by a lax condition of the mucous membrane of the ventricular cords and epiglottidean folds, with sometimes swelling, tumefaction, or submucous infiltration; by œdema or congestion of the proper muscular structure of the thyro-artenoid muscles, impairing the contractile power of one or both of them; by pressure upon the bronchi and trachea of external tumors, as, bronchocele, aneurism, intra-thoracic, or cervical tumors, etc., and when the pressure involves the recurrent laryngeal nerves, the vocal cord of the affected side will be found motionless; or, by the presence of epithelial growths, polypi, etc. Hoarseness likewise frequently follows overexertion in public speaking, singing, reading aloud, etc.

Persons who are more or less called upon to speak in public, and especially those whose vocal organs are very sensitive to changes of air from warm to cold, and from dry to moist, are prone to catarrhal attacks, hyperæmia of the vocal organs, relaxation and irritation of the fauces and back part of the throat, elongation of the uvula, a congested or relaxed state of the vocal cords, giving rise to a low husky or hoarse voice, frequently accompanied with dryness and irritation of the throat, more or less pain or soreness in speaking, and a feebleness of the vocal efforts. Those who speak in the open air, or within doors where a very slight draught blows upon the head and neck, or where the temperature is too low, are also liable to these difficulties, and which, if permitted to continue without treatment, will eventuate in follicular pharyngo-laryngitis. In these instances, there will be more or less change in the tone and character of the voice, it may be feeble, in a lower or higher key than natural, may be puerile like that of a child's or woman's, or rough and hoarse, squeaking, ragged, tremulous, and, sometimes, the speaker will be unable to utter a word, at some period during a speech, without first clearing his throat, or swallowing a draught of some fluid; more or less hacking cough also occurs.

Among singers, similar exposures and overexertions, are apt to give rise to a want of harmonious action in the tonic contraction of the vocal muscles, so that the persons will be unable to ascend or descend the notes of the scale, "breaking down," as it is termed, at some part of the scale, whether the lower, the middle, or the upper, but principally, of the middle, in either the chest or falsetto

registers. The varieties of voice usually affected, are, the tenor, contralto, and soprano, the last two in females, and the first in males,—and the compass of the voice is diminished by several notes in some part of the diatonic scale.

When the middle notes are imperfect, and the person is required to ascend the scale slowly from the lower notes, the tension and parallelism of the vocal cords are found to be good and without fault; as the middle notes are reached, both are altered, for the tension becomes irregular and the parallelism is destroyed, especially if the tension of one cord is good and the other is imperfect, for then the fissure of the glottis corresponds to a small, thin segment of a large circle. As the notes now rise, the natural tension of the cords, or of the affected cord, is regained, and both perform their proper vibrating function to the termination of the notes of which the singer has been accustomed to go, whatever that may be. When both cords are affected in the middle notes, they equally lose their power of tension, and consequently of vibration, at that part of the scale, and parallelism, although it may not be wanting, is powerless for perfection of melodious, or rather, harmonious sounds. (*Gibb.*)

There are other conditions of voice, as, double voice, or where it alternately becomes tenor and bass, and stammering, etc., which, however, will not be considered in this work.

A *laryngoscopic examination* will detect in nearly all instances the causes of these vocal peculiarities, and which will generally be found to consist of one or several of the morbid conditions of the vocal organs, named above, as causes of hoarseness. After inspecting the several parts of the larynx in a state of rest, the patient should be requested to utter sounds or notes, and especially those in which a failure has been noticed, that the examiner may observe the action of the vocal cords and their accessories. The patient should also be desired to inspire and expire deeply, in order that the expansion and closure of the glottis, or the extent of these movements, may be ascertained.

The *treatment* in these cases consists in carefully showering the cords and walls of the larynx and trachea with one of the solutions heretofore named, for the purpose of restoring these parts to a healthy condition, as, of Nitrate of Silver, Sulphate of Zinc, Tannin, Chloride of Gold and Soda, Golden Seal and Geranium, etc.; and treating ulcerations, foreign growths, œdema, etc., by the means already named. In some instances of obstinate relaxation of the cords, they may be daily, or semi-daily, showered with two or three minims of a weak solution of Strychnia. In the selection of the proper agent for application to the larynx, etc., considerable judgment is required,

as, what will benefit one patient may augment the symptoms with another.—In many instances, Faradization applied direct to the vocal cords, to various parts of the neck, and to the upper part of the spinal column will prove advantageous. Any abnormal condition of the fauces should be treated by gargles or topical applications, as may be required; strengthening relaxed mucous membranes by the infusion of Golden Seal and Geranium, or other toni-astringent solutions. In some instances, external applications to the throat may be advantageously employed, especially the Belladonna Plaster; counter-irritation is sometimes useful, especially when congestion or chronic inflammation is present; in other cases, it is seldom called for, and may produce debilitating and injurious results.

The diet should be carefully regulated, and gastric acidity, or a disposition to acid eructations, which exert such an unhealthy reaction upon the mucous membrane of the fauces and superior part of the larynx, must be promptly corrected by the Compound Powder of Charcoal, or other antacid or neutralizing agents. A proper attention must be paid to the skin, bowels, and kidneys. The body, and especially the feet, should be warmly clad, as well as the back of the neck and upper part of the back; exposures to cold or dampness must be avoided, and the voice should not be used more than is absolutely necessary for ordinary purposes, but should be kept in a state of rest and quiet until a cure is performed. Moderate physical exercise may be taken daily.

In most instances, constitutional measures will be required, according to the indications present,—chiefly tonics and alteratives. A rheumatic, scrofulous, or syphilitic dyscrasia, will require the appropriate remedies for these affections. In weak, anemic subjects, with want of tension of the cords, the Citrate of Iron with Strychnia, will be found useful as an internal agent.

Although not exactly in place at this part of the work, yet I wish to make few remarks concerning what is generally termed “WEAKNESS OF THE VOICE AND CHEST,” a condition that may occur at any period of life, but more usually in early life previous to puberty, and in middle age. It is ordinarily associated with a torpid condition of the liver, and of the digestive organs, habitual constipation, or exhaustion from excessive discharges, and is sometimes a result of excessive heat or cold. Sedentary persons, young females and, those who stoop a great deal, are especially disposed to it. The *symptoms* are, weakness and aching sensation of the chest, a dull pain in the chest behind the inferior part of the sternum, or else,

behind its upper third. Speaking or reading produces a tired sensation of the chest and vocal tube, a feeling in the larynx as if it were strained, and sometimes a transient, short, and hurried respiration. Breathing is slow and languid, with occasional long inspirations, and, in some instances, the patient complains that it is an effort to breathe. The patient becomes listless and has no desire to enter into conversation, and seldom utters more than a "no," or, a "yes," when spoken to. Occasionally, there will be slight palpitations or feebleness of pulsation, and a reduction of the beats to sixty per minute. The skin is commonly dull and pale; and the urine deposits an excess of urates, frequently mixed with oxalate of lime crystals.

No disease of the lungs or air-tubes can be detected by the most careful examination, except that the chest does not expand to its full extent in breathing; percussion elicits a clear sound; and auscultation detects a natural but weak respiration, and diminished intensity of the vocal resonance. The laryngoscope reveals no abnormal condition of the larynx or trachea, except, perhaps, a paleness of the laryngeal mucous membrane, and a general relaxation of the faucial mucous membrane. There appears to be a depressed nervous influence of the lungs and vocal apparatus,—an enfeebled action of the pneumogastric and laryngeal nerves, probably owing to some derangement of that part of the spinal nervous system which supplies the throat and chest with nervous energy and power.

The *treatment* consists in effecting a healthy action of the liver and digestive organs, and in giving tone to the nervous system. To arouse the liver, and stimulate it to normal action, Podophyllin, Oleo-resin of Iris, Leptandrin, Sanguinarin, etc., may be employed as named in the treatment for affections of the liver,—for the digestive organs, some of the agents named in the treatment for affections of the stomach may be used, especially, Hydrastin; Alcoholic Extract of Aletris, Strychnia, Citrate of Iron and Quinia with Strychnia, Oleo-resins of Ptelea, and of Xanthoxylon, etc., and if there is much acidity present, alkalis or absorbents will be required.

Nutritious but moderate diet; *cool* shower baths to the back and chest, together with occasional alkaline bathings of the surface; attention to the condition of the urine; moderate exercise daily in the open air; the maintenance of an erect position, the shoulders being thrown backward; and Faradization to the nape of the neck, and on each side of the cervical and dorsal portions of the spinal column, will aid materially toward a thorough and permanent cure.

ŒDEMA OF THE LARYNX.

Œdema of the Larynx, also termed Œdema of the Glottis, consists in an effusion of a serous or fibrinous character in the sub-mucous cellular tissue of the parts. The disease may be limited to the upper parts of the larynx, implicating the aryteno-epiglottic folds, and not extending to the rima glottidis; sometimes it extends as far as the glottis, involving the above-mentioned folds and also those of the ventricular cords. Occasionally, it involves only the membrane covering the false cords, producing a dangerous form of obstruction; and, in a few instances, it is confined to one side of the larynx. Laryngeal œdema is evidently an inflammatory affection, being associated with acute laryngitis, or occurring as a consequence of other laryngeal affections, and frequently manifesting itself during the course of other maladies, as, measles, scarlet fever, small-pox, typhus and typhoid fevers, etc. It may also be induced by the inhalation or presence of irritating vapors or bodies, as well as by exhausted or enfeebled conditions of the body. Although frequently termed "œdema of the glottis," the true glottis is never involved in the œdema.

Dr. G. D. Gibb, divides œdema of the larynx into two varieties, viz.: *Supra-glottic œdema*, and *sub-glottic œdema* of the larynx. 1. *Supra-glottic œdema* is situated above the glottis, and may be confined to only a part of the larynx, one side of this organ being puffed out and swollen, and the slit-like aperture of the true glottis converted into a curve; it may also involve the aryteno-epiglottidean folds, as well as the ventricular cords, only a vertical chink at the upper passage being noticed. Most generally the inflammation is low and asthenic, and is confined to the tissues internal to, or beneath the membrane. It occurs under various circumstances and conditions, is frequently coincident with other maladies of the air-passages, and may, even in healthy persons, attack suddenly during the night, and cause death in a few hours. It sometimes arises suddenly as a forerunner or primary symptom of Bright's disease, when its early diagnosis is of great importance, and the profession can not be too soon made aware of it,—in such cases, albumen may be detected in the urine, and the œdema is occasionally attended with aphonia.

The *symptoms* are, at first, a "sense of uneasiness in the larynx, and a continual effort on the part of the patient to expel, by means of a forcible expiration, mucus or other matters which appear to him to be clogging the laryngeal orifice; he also frequently en-

deavors, by repeated attempts at deglutition, to disembarass the upper part of the throat of some phlegm, or extraneous body which he imagines to have lodged in that situation. The voice is, at the same time, rather hoarse, but respiration remains for the present unimpeded. In the course of a few hours, or of two or three days, according to the rapidity with which the disease advances, the voice becomes hoarser, or sharp and stridulous, and there is occasional difficulty of breathing, more particularly in the act of inspiration; this is not permanent, however, but is succeeded by strong expiratory efforts, which by expelling a little glairy mucus, soon render the respiration tolerably free. If the disease remains unchecked, the dyspnœa in a short time becomes permanent, or offers only slight remissions; the patient sits upright in bed, with the head thrown back, the shoulders elevated, and the whole of the respiratory muscles convulsively engaged in endeavoring to draw air into the chest, while the power of expelling the air with facility still continues. The almost constant dyspnœa is aggravated from time to time by spasmodic attacks of suffocation, which occur more frequently as the obstruction to respiration increases, and the patient dies either in one of these attacks, or, as more commonly happens, in the intervals between them, when we should expect that the air, by penetrating into the chest, would reanimate and restore him." (*Bayle and Ryland.*)

In the commencement there is no derangement of the general health, unless some other disease be present, but, as the œdema progresses the pulse becomes weak, soft, small, quick, and irregular, and the system betrays imperfect oxygenation of the blood. There is no difficulty in swallowing, unless the epiglottis is involved; no pain or soreness is complained of, but a sense of constriction in the laryngeal region; there may or may not be inflammation of the fauces; the voice is at first hoarse, then sharp and hissing, and afterward croupal or extinguished; expiration is performed with comparative freedom, while inspiration is prolonged, difficult, and distressing; and a dry, hoarse, and convulsive cough, with paroxysms of suffocation, causing the utmost agitation and distress, is generally present. The intellect and the digestive functions remain unimpaired.

Great care is required in the *diagnosis* of this disease, that its true character be not overlooked. Its distinctive features are, the difficulty of drawing air into the chest, the almost total absence of pain, heat, or soreness in the region of the larynx, and the peculiar sensation of fullness about the upper part of the throat, conveying to the patient the idea of there being a foreign body in

that situation, the removal of which is attempted by repeated efforts at swallowing. A *laryngoscopic examination*, when it can be made, will enable us to detect the difficulty. Two tense, smooth, semi-transparent, globular or oval swellings will be seen, seated immediately behind the epiglottis, and sometimes partly concealed by this cartilage, which meet in the center with a furrow between them, generally more prominent in front. If one side only is affected, a prominent swelling will be observed projecting across the larynx. According to the extent and stage of the œdema, is a view permitted of the vocal cords or of the parts beyond the true glottis. The œdema reaches its highest degree in the ventricular cords, where the strata of areolar tissue are but loosely covered by the mucous membrane, and hence is explained the nature of the urgent dyspnœa which is ready to strangle the patient. The consistence of the swelling can often be determined by the introduction of the finger into the mouth, but, as sometimes seen, it may be slightly corrugated and loose on its surface. The epiglottis may also be œdematous, and is frequently erect; but remains unaffected when the œdema has not attacked it.

Supra-glottic œdema of the larynx consists in a serous effusion in the submucous cellular tissue of the parts above the glottis, the result of inflammation commencing in this tissue, and not in the mucous membrane. A *post-mortem examination* will detect the tumor or tumors, obstructing the area of the glottis more or less completely, according to their development. The swellings are generally of a pale-yellow color, and devoid of apparent vascularity, and are formed by the effusion of limpid serum into the submucous tissue of the lips of the glottis, and of the folds of mucous membrane which connect the arytenoid cartilages with the epiglottis, as well as into the adherent surface of the mucous membrane itself in the same situation. The œdema may extend to the base and lateral edges of the epiglottis, and to the mucous membrane lining the cricoid cartilage. The posterior and external surface of the larynx, the base of the tongue, and the tonsils, frequently participate in the disease. If the œdema has progressed slowly, the effused fluid is apt to be of a sero-purulent nature. In most instances, tumefaction, varying in size from a sparrow's to a robin's egg, with closure of the upper or false rima glottidis, and serum, are alone noticed.

Since the discovery of the laryngoscope, the *prognosis* in supra-glottic œdema is much more favorable than it was previously; still, a cautious reserve should be maintained, especially in those cases where the symptoms are very severe, or, in which it is impossible

to employ the laryngeal mirror. Although its symptoms are apparently more dangerous than the sub-glottic variety, it is much more tractable to treatment by early scarifications. In laryngeal phthisis, if œdema of the larynx manifests itself, although relief may sometimes be afforded, the case is hopeless.

The *treatment* of supra-glottic œdema of the larynx consists in freely scarifying the œdematous ventricular cords, edges of the epiglottis, aryteno-epiglottidean folds, etc., thus allowing the effused serum, which is the whole cause of the difficulty in breathing, to escape. The operation is performed with scarificators expressly made for this purpose, and is conducted with the aid of the laryngoscope. If necessary, the scarifications may be repeated every four or five hours. Dr. Gibb advises a properly curved bougie, half an inch in diameter, to be passed into the larynx after scarification, for the purpose of compressing the swellings, and forcing out the serum through the punctures made. After scarifying, the vapor of warm water inhaled, will favor the evacuation of the serum; the pulverized fluid or spray of a very strong solution of Tannin may be inhaled in some cases, with advantage, or, of Geranium, Rhatany, etc., and which may be repeated once or twice a day,—or these astringent solutions may be applied by means of a curved brush. In slight cases of œdema, they will, alone, frequently effect a cure. After all danger has passed away, it will be advisable to administer the Iodide or Bromide of Potassium or of Ammonium, for some time, in order to remove any tendency to a renewal of the attack; and a solution of the Chloride of Gold and Soda may also be applied to the parts affected, once or twice daily, by means of a curved brush.

When the means above-named fail, the symptoms rapidly becoming more and more severe; or, when the laryngoscope can not be used, nor scarification be performed; or, if the patient lie in the recumbent position in an exhausted and motionless condition,—*tracheotomy* must be performed. This operation should not be postponed for too long a period; it is preferable to laryngotomy, as it affords rest to the affected larynx, and prevents any irritation that might occur from the constant passage of the air forward and backward. Dr. Gibbs prefers the opening into the trachea to be made *immediately below the cricoid cartilage*, (provided there are no dangerous obstacles present), instead of in the crico-thyroid space.

Syphilitic laryngitis often terminates in supra-glottic œdema, the cavity of the cricoid cartilage being frequently filled up by fibrinous material, in which case, the above-named operation may prove of service.

2. *Sub-glottic œdema of the larynx* is situated below the glottis, and is wholly distinct in its nature and character from that existing above the glottis, the effused material being invariably fibrinous. Dr. Gibb is, I believe, the first person who has described this form of laryngeal œdema. Its *symptoms* are similar to those of the preceding form, as, more or less urgent dyspnœa, hoarse laryngeal whisper, laryngeal cough, a peculiar croupy stridor during inspiration, with great distress, much mucus secretion, etc. The respiration is more stridulous, wheezing and croupal, than the supra-glottic form.

Dr. Gibb remarks, "In my dissections I have sometimes found a thin yet distinct layer of areolar tissue between the cricoid cartilage and mucous membrane, and sometimes it is somewhat lax; under such circumstances, if inflammation were present, a submucous effusion would be liable to occur; but as the resistance is greater below than above the glottis, serum is exuded from the surface of the membrane, and fibrine remains behind." After referring to the opinion of several writers, to the effect that there can be no subglottic œdema, because as no layer of cellular texture exists there, there can be no infiltration, he observes:—"The views enunciated by those whose writings have been quoted, are held by all pathologists, and it might seem an unwarrantable presumption on my part to dispute their correctness; indeed, such is not my intention; but as a searcher after truth, while I acknowledge that, as a rule, œdema of a supra-glottic nature rarely extends below the true glottis, yet the laryngoscope has revealed that isolated or exceptional cases do sometimes occur. If the two forms co-exist, it is not by extension of one to the other, for the simple reason that the effusion in one is chiefly serous, and in the other fibrinous; and, as has been most correctly, and I may say indisputably observed, the true cords themselves do not become œdematous, and therefore the one can not extend or pass into the other.

"*Laryngoscopic examination* can alone determine which form of œdema is present; it will reveal a larger or smaller swelling, or two swellings, below the glottis, and surmounted, as it were, by the vocal cords. The œdema occupies the sides or posterior part of the subglottic region, and, as a rule, never extends farther than the commencement of the first ring of the trachea.

"Subglottic œdema is a more dangerous disease than the other form. Scarifications would be useless in it, from the nature of the effusion, and in the great majority of cases, (although hitherto not suspected), it has no doubt demanded early tracheotomy. It is the

form, also, more likely to demand the permanence of the fistulous opening, and probably has obliterated the passage upward from filling up of the calibre of the cricoid cartilage. Additional information will be very desirable to complete its clinical history." (*Gibb*.)

The *treatment* consists in anodyne poultices or fomentations to the throat, and the internal use of Iodine, Iodide of Potassium or Ammonium, etc., to cause absorption of the effused material, together with showers of solution of Nitrate of Silver, Sulphate of Zinc, etc., to the subglottic region daily. When the symptoms are acute, the vapor from hot water may be inhaled, or, from some anodyne infusion; and, internally, Acetate of Ammonia, Veratrum Viride, Gelseminum, Lobelia, etc., may be administered. To prevent depression or sinking, small quantities of brandy, or other stimulant should be given from time to time, as required. When the symptoms are urgent, tracheotomy should be performed without delay.

SACCHARINE THROAT.

This is a new and distinct malady, first made known to the profession by Dr. Gibb, and which is chiefly met with among those in middle life. It is dependent upon, or associated with, certain changes which the system is undergoing, especially a transformation of the saccharine element, *hepatine*, or *amyloid substance* into fat and its compounds, which produce, either a state of corpulency or a fatty degeneration of the tissues, associated with an atheromatous ulceration of the lining membrane of the cerebral and larger blood-vessels.

The *symptoms* are peculiar. If the vocal apparatus is involved in the change going on in the system, there will frequently be dryness of the throat; a huskiness of the voice; an augmented secretion from the fauces; great irritation of the throat, often requiring some previous preparation of it before the laryngeal mirror can be used; sometimes this irritability of the throat and larynx occasions a harassing cough; the tongue is slightly furred; and the patient complains of a sweet taste in the mouth, sweetness of the saliva, and that food frequently tastes as if it were mixed with sugar. If the fauces be examined, a thin layer of mucus or gelatinous matter, with a predominance of the fatty element, will be observed covering the mucous membrane; if this be removed, in many instances, the parts will have a greasy appearance, and the follicles will be found somewhat enlarged and apparently

secreting an oily fluid. The patient frequently hems very loudly to clear his throat, and the noise is sometimes of a barking or cracked character; and which is due to calcareous degeneration with a mixture of the fatty, associated with true structural change in the yellow elastic tissue of the vocal cords. The face has a greasy appearance, the nose and lips are slightly swollen, the eyes are bright and watery, and there may be an arcus senilis or annulus adiposus, and the conjunctivæ look fatty. The skin of the face is smooth and even, sometimes covered with many small red vessels, ramifying in patches of a stellated form; there may, or may not be corpulence; and the patient complains of a cold which obstinately continues to annoy him, and to which he is very subject. Sometimes sugar will be detected in the urine, but not always.—The pathognomonic symptoms are, the peculiar (atheromatous) expression, the follicular affection, and the peculiar nature of the secretion with the sweet taste invariably present.

A *laryngoscopic examination* will detect the laryngeal mucous membrane congested, relaxed, and freely secreting, with enlargement of the follicles; the faucial mucous membrane will have a muco-gelatinous or oily glistening appearance, with general relaxation, and congestion, and secreting freely—together with more or less prominence of the follicles.

The *treatment* which Dr. Gibb has found the most useful, is the internal use of Iodide of Ammonium, Bromide of Ammonium, and Nitrate of Uranium, conjoined with some good vegetable astringent tonic, as, the Syrup of Matico in doses of one or two drachms,—and, also, an alterative and astringent local treatment. In the spasmodic cough and dyspnoea, he recommends Cypripedin in doses of three grains, as a sedative and alterative. And to act upon the biliary organs, and, at the same time, maintain regularity of the bowels, he advises Podophyllin and Leptandrin, to be administered every other day.

It is of the utmost importance to regulate the diet, carefully abstaining from all malt beverages, and avoiding too much farinaceous food.—I believe, that in these cases, a judicious combination of the measures named in the treatment of Softening of the Brain, and that of Follicular Pharyngo-laryngitis, will be found useful. The earlier the treatment is commenced, the more prompt and desirable will be the beneficial results.

There are several other affections of the larynx which have been fully described in several monographs upon throat and laryngeal

diseases, and to which the reader is referred. But they occur so rarely that a passing notice is all that is deemed necessary in this work. These are, *Cancer of the Larynx*, *Hydatids in the Larynx and Trachea*, *Gout of the Larynx*, *Deformities of the Larynx*, *Ossification and Calcification of the Cartilages*, etc. Ossification is a natural process occurring in old age, phosphate of lime being largely deposited into the cartilaginous structure, so that it becomes converted into the elements of true bone. But when the cartilages become hardened at an early period of life, it is not from ossification, but most commonly from calcification, carbonate of lime being deposited in the cartilages of the larynx, and generally associated with fatty degeneration of the parts thus calcified. This form of disease is apt to be present among those who are affected with saccharine throat. It is an indication of premature old age, or premature decay of the system, from fatty transformation, and the patient is liable to sudden death at any time from rupture of some of the softened arteries of the brain. In calcification of the larynx, the voice is loud, loose, and husky, or has a feeble, or, sharp-brassy sound, and is often associated with a noisy, barking cough. The vocal cords are seen in the laryngeal mirror to be undergoing atheromatous changes, presenting an irregular patchy appearance with a mixture of yellow and chalky white. The cartilages are brittle, and mixed with minute particles of fat, oil, and cholesterine. The *treatment* is the same as described for Saccharine Throat. Dr. Gibb believes that small doses of Nitrate of Uranium dissolve the calcareous material already deposited in the larynx and blood-vessels.

Chronic Tracheitis may generally be detected by the laryngeal mirror, and requires the same treatment as named for Chronic Laryngitis. The symptoms are similar to those of the latter disease, with the exception of the existence, in the tracheal disease, of a constant pain or tightness at the lower part of the neck, or behind the upper part of the sternum, in most instances. The voice is not impaired unless laryngeal disease be likewise present.

CHRONIC BRONCHITIS.

Chronic Bronchitis is one of the most common diseases met with in this country. It may occur as the result of a neglected or badly treated acute bronchitis, as well as laryngitis, or tracheitis; and it

frequently follows whooping-cough, diphtheria, measles, and other exanthematous affections, protracted biliary maladies, as well as the recession of certain cutaneous diseases. Sometimes it is associated with organic disease of the heart, or tubercular lung disease; and, again, it may be *caused* by a constant exposure to irritating powders, which are inhaled, as, among stone-cutters, millers, workers in metals, etc. But its most common cause is cold, or sudden exposures from heat to cold, from a dry to a moist atmosphere, and vice-versa. It is frequently the case that the disease does not manifest itself during the warm summer months, but only in the winter, and especially when this season is cold, damp, and changeable,—and hence it has been called *Winter Cough*; at other times, there is more or less cough and expectoration even during the warm seasons. It is frequently associated with rheumatism, often disappearing when the rheumatic affection is severe, but returning upon its subsidence.

The *symptoms* of chronic bronchitis vary according to the duration and extent of the affection. There is little or no fever, but sometimes an acceleration of the pulse. The most characteristic symptom is cough, which is frequent and habitual, and is more troublesome and annoying during cold and changeable seasons; but, in the early stage of the malady, it is absent during pleasant, warm weather; indeed the disease may continue in this manner for a life-time without causing any serious consequences, or without the general health suffering any. Frequently, however, it is of a more aggravated character; the cough is more or less persistent and troublesome, with expectoration of a viscid mucus, and both cough and expectoration are apt to be more distressing at night, and in the morning, particularly if the feet, moist with perspiration, come in contact with cold sheets, a cold floor, etc. The cough sometimes occurs in violent paroxysms, and especially when irritating vapors, or floating particles of matter are inhaled, and this is more especially the case when the bronchitis is associated with a laryngeal affection; the cough is somewhat relieved upon the expectoration occurring. At first the expectoration is a thin, transparent, adhesive, frothy mucus, devoid of taste or smell, but, after a longer or shorter period, it becomes thick, muco-purulent, greenish, or yellowish white, sometimes streaked with blood, and in the advanced stages of the disease, it is copious and fetid. When copious, it is termed *bronchorrhœa*. Frequently, small particles of sebaceous matter from the faucial and pharyngeal follicles will be seen in the expectoration, and which have been mistaken for tubercular matter. A dark, blackish, or bluish coloration of the sputum is due to particles of dust, smoke, etc., inhaled by the patient. Calcareous

concretions are likewise occasionally met with in the expectoration of chronic bronchitis.

The cough may be short and hacking, or it may be loud and ringing, and, sometimes, it is dry, being unattended with expectoration. In some instances, the chest will be free from pain; while, in others, there will be more or less soreness or pain.—In the rheumatic variety of bronchitis, coughing is apt to produce a rough, scraping, painful sensation in the bronchi, and the urine will contain an excess of urates of soda and lime.—If the disease is allowed to progress, the skin becomes dry and harsh, the tongue coated, especially in the morning, the appetite more or less impaired, the bowels irregular, and the urine high-colored. Eventually, the pulse becomes quick, weak, and small, the breathing short, hurried, and laborious, particularly on any exertion, with emaciation, night sweats, pale face, hollowness of the eyes, purplishness of the lips, great debility, colliquative diarrhea, and soreness of the nose and lips, and which condition may continue from one to several months, and then prove fatal. The last stages may be mistaken for phthisis, and can only be discriminated from it by auscultation and percussion.

Percussion obtains a clear vesicular resonance, unless the disease be complicated with some other affection of the lungs, as, tuberculosis, solidification, etc., when there will be a corresponding dullness in proportion to the density of the lung. If there be dilatation of a bronchial tube, which may be the case if the disease has been of long standing, there will often be dullness around the dilated part. The vesicular resonance is sometimes temporarily impaired by the presence of an excessive quantity of secretion, but when this is removed by coughing or otherwise, the slight dullness disappears.—Auscultation will detect sounds depending upon the condition of the bronchial mucous membrane, and the quantity of its secretions, as, either dry or moist bronchial rales, or both, variously combined, and which can be heard especially at the lower and back parts of the chest on either side. The dry or sibilant rale, indicates a want of secretion; the mucous rale, the presence of secretion; and large crepitation or gurgling, relaxation and atony of the mucous membrane. Bronchitis may be present, however, without any rales being heard. When it is complicated with other lung diseases, the physical signs peculiar to these diseases will be present.

When bronchitis has associated with it, dilatation of the bronchial tubes, there will not only be dullness on percussion, as already alluded to, but there will be observed, on auscultating, a diminu-

tion in the intensity and duration of the inspiratory resonance, and an augmentation in those of the expiratory sound; if the dilated tube be empty the respiration will be bronchial or cavernous,—if it contain fluid, the moist bronchial or bubbling rales will be detected at irregular periods, and of variable loudness. Sometimes, we also have bronchophony, pectoriloquy, and bronchial or cavernous cough, depending upon the character and extent of the dilatation, and these signs may mislead to a supposition of tuberculous disease in the lungs. But by bearing in mind that dilatation is generally preceded for a long time by cough and expectoration, and that the cavity ordinarily precedes the dullness, while in phthisis the dullness precedes the cavity, we may be better enabled to form a correct diagnosis, more especially when a careful investigation of the physical signs, as well as of the symptoms present, are made—debility, emaciation, pallor, thoracic pains, hemoptysis, night sweats, hectic fever, etc., being more commonly the indications of consumption. However, dilatation and tuberculosis may co-exist. (*See Note*, page 539, *sections 14 and 25.*)

Patients are frequently met with who have labored under chronic bronchitis for many years, having a wheezing respiration, and which becomes hurried by exercise, with a somewhat leaden appearance of the complexion indicating a lack of sufficient oxygen, inspiration being somewhat laborious and expiration prolonged. There is no acceleration of the pulse, nor pain in the chest, but they have a peculiar nervous susceptibility, are subject to dyspnoea or distinct paroxysms of asthma, often attacking them shortly after having retired to rest; their sleep is more or less disturbed; they become unfit for active duty; the heart becomes oppressed and dilated; and they die either from acute bronchitis, dropsy, or consumption.

The *diagnosis* of chronic bronchitis, is, as a general rule, not difficult. The principal and important points, however, which we are to determine, are, as to the complication or non-complication of the disease with others, as, dilatation of the bronchial tubes, chronic pneumonia, emphysema, tubercular phthisis, or chronic pleuritis, etc.; and this can only be effected by a careful observation of the symptoms, and of the physical signs, as these will generally be found present and in accordance with the nature of the complication. When tubercular phthisis is present, there is almost always more or less lesion of the bronchi, and the supervention of bronchitis and emphysema; and the most difficult cases to diagnose are those where the phthisis is ushered in, and its symptoms are masked by bronchitis. But the symptoms which are common to

phthisis and which occur exceptionally in bronchitis may aid us in forming our diagnosis; thus, in phthisis, there are acute pains at the upper part of the chest of one side, or beneath the scapula, the breathing is more or less hurried, the pulse is quick, febrile symptoms often manifest themselves, hemoptysis is common, and the bronchial rales are more usually observed at the anterior upper part of the chest, and usually on one side only. A microscopic examination of the sputum will also find evidences of tubercle and disintegrated lung tissue, which are absent in uncomplicated bronchitis; and these evidences of lung disease may be observed *before* any auscultatory signs of phthisis can be heard.

The *prognosis* in chronic bronchitis is usually favorable as long as the expectoration consists chiefly of mucus; the more this becomes purulent, the less favorable is the prognosis, more especially when it is profuse, with constant dyspnoea, rapid pulse, emaciation, hectic fever, night sweats and colliquative diarrhea; though cases have terminated favorably where the expectoration was somewhat purulent. A dark red, or raw appearance of the tongue, with aphthous ulcerations about the mouth and fauces, are very unfavorable symptoms. The presence of a scrofulous diathesis, or a tendency to phthisis, should render us cautious in our prognosis. Advanced age is unfavorable, and also an acute attack rapidly coming on during the course of the chronic affection. When the bronchitis is complicated with other affections, the prognosis will depend upon the character of the complication, its duration, its extent, and its influence upon the bronchial disease.

The *post-mortem appearances* observed, are, not the vivid red color of the mucous membrane as seen in the acute form, but a livid, violet-colored, yellowish, or brownish tint; mucus and other secretions will be found in the bronchial ramifications, and sometimes the tubes will be filled with secretions of a fibrinous character. Dilatation of one or more of the bronchial tubes is frequently an accompanying lesion. From derangement of the nutrition of the bronchial mucous membrane, this tissue may be thickened, indurated, softened, or ulcerated. Thickening sometimes exists to such an extent as to obliterate the lesser bronchial branches, and to contract or diminish the diameter of the larger ones. If complications exist, the appearances will be in accordance with the nature and extent of the accompanying lesion, and the organ or organs affected by it.

The *treatment* of chronic bronchitis is both local and general, and must be regulated by circumstances, being more active as the symptoms are more severe. Among the local measures that have been

found useful are counter-irritants applied to the external surface of the chest; thus, the Compound Tincture of Camphor, the Compound Liniment of Oil of Amber, or the Compound Liniment of Turpentine, may be rubbed, two or three times daily, over the chest and back, and especially along the cervical and superior half of the dorsal vertebrae. The following will also be found a very useful application: Take of Oil of Turpentine three fluidounces, Oil of Spike four fluidrachms, Oil of Sassafras, Oil of Amber, each, two fluidrachms; mix. In conjunction with this external application, inhalations will be found very advantageous; thus, the vapor from heated vinegar and water, equal parts, or from the same fluid mixture medicated by sedatives, astringents, or stimulants, as may be required. The sedative mixture may be required in case there is great excitability or irritability of the air-tubes; the astringent, where there is an excessive expectoration; and the stimulant or expectorant, where the cough is dry, or expectoration is difficult.—A list of inhaling mixtures will be given at the close of the present treatment.—Nitrate of Silver inhaled, in the manner heretofore explained on page 564, will be found valuable; or, it may be prepared as follows: Take of Lycopodium five drachms, Nitrate of Silver one or two drachms; dissolve the Nitrate in a sufficient quantity of warm soft water, or distilled water, to form a stiff paste with the Lycopodium. Place this paste in thin layers on plates of glass, or on shallow plates; cover it so as to protect it from dust, and from the action of the light, and set the whole in a moderately warm and dry location; when it is thoroughly dried, pulverize it, and keep it in blackened vials.—Solutions of Nitrate of Silver showered into the air-tubes will also be of great efficacy.

The introduction of finely-powdered medicated fluids into the bronchial vessels, by means of nebulizers or spray-producing instruments, will be found exceedingly valuable in the treatment of bronchitis. The remedies that are hereafter recommended for inhalation may mostly be made into solutions or infusions and used for this purpose; some care, however, is required to regulate the strength of the preparations, and the quantity employed at a sitting. A very useful agent in many cases of bronchitis is Carbolic Acid, one part of which may be dissolved in four parts of Alcohol; to use it, add one fluidrachm of this mixture to two parts of Water, and inhale the fine spray from this, once or twice every day, using about a fluid-ounce at each sitting.—Some of the articles heretofore named as applications to the lining membrane of the air-passages, may also be employed in this malady.

In most instances, the above measures will be all that will be

required to effect a cure; but, sometimes the cough will be quite troublesome, for which sedatives and nauseant-expectorants may be advantageously administered; one of the following preparations will be found serviceable:—1. Take of Hydrochlorate of Ammonia, Extract of Liquorice, each, two drachms, Extract of Hyoscyamus half a drachm, Syrup of Tolu one fluidounce, Acetate of Sanguinarina two grains, Water six fluidounces; mix, and dissolve. The dose is a teaspoonful every hour.—2. Take of Honey, Olive Oil, Sweet Spirits of Nitre, and Lemon Juice, each, half a fluidounce; mix. The dose is a teaspoonful several times a day, or whenever the cough is severe.—3. Take of Fluid Extract of Stillingia one fluidounce, Compound Syrup of Spikenard two fluidounces, Tincture of Black Cohosh one fluidounce; mix. The dose is a teaspoonful three or four times a day.—4. Take of Tincture of flower stalks of Mullein, Tincture of Black Cohosh, Tincture of Balm of Gilead Buds, each, half a fluidounce, Syrup of Tolu one fluidounce; mix. The dose is a teaspoonful every hour or two.—5. When the disease occurs in a rheumatic patient, the following cough mixture will prove advantageous: Take of Tincture of Black Cohosh, Tincture of Gelseminum, each, six fluidrachms, Tincture of Aconite Root two fluidrachms, Fluid Extract of Wild Cherry one fluidounce and a half, Fluid Extract of Stillingia six fluidrachms; mix. The dose is from thirty to sixty minims every one, two, or three hours.—6. Take of Gum Ammoniac twenty-four grains, Ipecacuanha six grains, Muriate or Sulphate of Morphia two grains, Carbonate of Ammonia twenty-four grains, Mucilage of Gum Arabic a sufficient quantity; mix, and divide into twelve pills. Coat the pills with a varnish of Tolu dissolved in Chloroform, and keep in well-stopped vials. Dose, two, three, or four a day, in cases where the bronchial secretion is viscid and expectorated with difficulty. Preparations from various other articles have also been used with benefit, as, Tincture of Larch, Lobelia, Indian Turnip, Senega, Ipecacuanha, Canada Balsam, Bitter Candytuft, Matico, Eucalyptus, Ammoniacum, Sulphate of Quinia, etc.

If the expectoration be too profuse, astringents may be used in conjunction with the other agents, as, Alum, Geranium, Tannin, Beth Root, etc.

Emetics will be found a very valuable class of agents in this disease, especially when of long standing, or when the symptoms are obstinate and severe. The Compound Powder of Lobelia may be administered for this purpose, and be repeated every week or two, according to the strength of the patient, until the disease is cured, or has become very much improved. And when the bronchitis fol-

lows some other disease, or occurs primarily in a scrofulous system, the Bromide or Iodide of Ammonium, in conjunction with the Compound Syrup of Stillingia, will be found an invaluable constitutional medication.—Diarrhea may be met by astringents; the Tincture of Chloride of Iron, twenty drops in a wineglassful of Blackberry Root infusion, repeated three or four times a day, will be found very efficacious. In some cases, a mixture of Geranium one grain, Camphor half a grain, Opium one-fourth of a grain, will prove useful,—this dose may be repeated as required, two or three times a day.—In dilatation of the bronchial tubes with moist rales, occasional emetics and nauseant expectorants will be useful, in connection with the local measures already referred to, and the employment, internally, of tonics and alteratives, as, Bromide of Ammonium, Sulphate of Quinia, Citrate of Quinia and Iron with Strychnia, etc.

The bowels should be kept regular, but not actively purged; acidity of the stomach should be corrected; the urinary secretion should be kept in as normal quantity as possible, and the diuretics employed should be of a stimulating, balsamic character, as, Canada Balsam, Balsam of Copaiba, Cubebs, Horseradish Root, Queen of the Meadow Root, Uva Ursi, etc. The surface of the body must be attended to, frequently bathing with an alkaline solution, and giving a Spirit Vapor Bath every two or three weeks, as the strength of the patient will permit. Exercise should be taken in the open air whenever the weather will permit; and flannel should be worn, especially in cold and damp seasons, in order to preserve an equable degree of temperature of the surface of the body, and, in cold weather, much benefit will be derived by drying and toasting the feet before the fire, or, by sleeping with a hot iron or brick to the soles of the feet. The sleeping apartment should be well ventilated, not have more than one or two persons occupying it, and its atmosphere should never be allowed to fall, during the night, below 60° Fahrenheit. And care should be taken in cold weather to protect the air-passages from the direct influence of a cold atmosphere, by wearing a handkerchief or other article over the mouth, when exposed to the open air. The general rules for diet, etc., heretofore mentioned are applicable in the management of this disease. When much debility is present, or, when the digestive functions are torpid or enfeebled, bitter tonics may be employed, and the moderate use of English Porter, Brown Stout, or Scotch Ale, at meal-time, will be found beneficial. By the adoption of the treatment just named, it will rarely be required for a patient to

remove to a warm climate, unless the disease be complicated with a tuberculous tendency of the lungs.

As inhalations are frequently of great value in the treatment of bronchial and pulmonary affections, I will give a list of some that I have employed with much advantage in these maladies. Those which require to be warmed in order to produce a vapor for inhalation, should be placed in a vessel, with a tube attached to be held in the mouth, or in the nostrils. Those which are volatile may be used in the same manner, or, a piece of sponge may be moistened with a teaspoonful or two of the fluid desired, and then be placed in a tumbler, from which the patient may inhale by holding the glass to the mouth and nostrils. Powders may be inhaled as heretofore named on page 564.

1. *For purulent expectoration.* Take of Gum Myrrh half an ounce, Gum Hemlock two drachms, Crude Pyroligneous Acid one fluidounce; mix, and dissolve by heat. A tablespoonful of this mixture may be thrown upon a hot shovel, and the vapors that arise be inhaled.

2. *Alterative and Stimulant.* Take of Nitre twenty grains; Common Salt one drachm; Hydrochlorate of Ammonia one drachm; Water half a pint; mix. Heat and inhale the vapor for ten or twenty minutes at a time.

3. *Soothing solution.* Take of Alcoholic Extract of Conium twenty grains, Camphor twenty grains, Tincture of Benzoin two fluidrachms, Water four fluidounces; mix. About two fluidrachms in a gill of hot water may be inhaled for ten or twenty minutes at a time.

4. *Alterative.* Take of Iodine six grains, Iodide of Potassium twelve grains, Alcohol one fluidrachm, Water three fluidounces; mix. One fluidrachm to be inhaled at a time. In some cases, No. 3 and No. 4, in proper quantity, may be added to six or eight ounces of Water, and the vapor be inhaled; the combination gives rise to effervescence.

5. Take of Iodine three grains, Iodide of Potassium six grains, Tincture of Lobelia one fluidounce, Tincture of Benzoin six fluidrachms, Ethereal Tincture of Conium one drachm and a half, Alcohol half a pint; mix. A drachm or two may be added to a gill of hot water, and the vapor be inhaled for ten or twenty minutes. Useful in tubercular phthisis.

6. *Astringent and Anodyne.* Take of Alcohol four fluidounces,

Naphtha one fluidrachm, Benzoic Acid half a drachm, Tannic Acid eight grains, Chloroform one fluidrachm; mix.

7. *Expectorant.* Take of Pleurisy Root half an ounce, Black Cohosh two ounces, Queen's Root one ounce, Lobelia half an ounce. Ipecacuanha two drachms, Diluted Alcohol one pint; mix. Two fluidrachms of the tincture may be added to half a pint of hot water, and the vapor be inhaled.

8. *Expectorant.* Take of Alcohol six fluidounces, Nitric Acid half a fluidrachm, Tincture of Tolu one fluidounce, Tincture of Camphor half a fluidounce, Oil of Bitter Almonds six minims; mix. A teaspoonful to half a pint of water.

9. *Soothing.* Take of Belladonna Leaves half an ounce, Black Cohosh two ounces, American Hellebore Root half an ounce, Aconite Root two drachms, Chloroform two fluidrachms, Diluted Alcohol one pint; mix. Use in the same quantity as the preceding, when there are febrile symptoms present.

10. *Astringent.* Take of Geranium one ounce, Beth Root one ounce, Golden Seal one ounce, Wild Indigo Bark one ounce, Diluted Alcohol one pint; mix. Used as the preceding, in relaxed conditions of the mucous membrane.

11. *Astringent.* Take of Geranium one ounce, Beth Root one ounce, Witch Hazle Bark two ounces, Balsam of Peru two drachms, Alcohol one pint; mix. Used as the preceding, in hemoptysis.

12. *Alterative.* Take of Chloride of Gold and Soda ten grains. Chlorate of Potassa one drachm, Sugar of Milk two ounces; mix. and reduce to an impalpable powder. Used in tubercular phthisis. inhaling the dust.

13. Take of Mullein Leaves two ounces, Meadow Sweet, Maiden Hair, each, one ounce, Stramonium Leaves half an ounce, Boiling Vinegar one pint; mix, and macerate for one hour. When cold, filter and add an equal quantity of Water in which half an ounce of Salt has been dissolved. Heat a small portion of this, and inhale the vapor for ten or twenty minutes each time. Useful in chronic laryngitis, tracheitis or bronchitis, with cough and irritability of the mucous membrane.

Many other agents and compounds have been used in inhalations in the form of vapor, as, Diluted Hydrocyanic Acid; Chlorine; Chloroformyl; Creosote; Nitric, Acetic, and Hydrochloric Acids; Nitrous Gas; preparations of Bromine; pure Deodorized Alcohol; Acetate of Zinc; Nitrate of Bismuth; Aqua Ammonia; Oil of Turpentine; Canada Balsam; solution of Hydrochlorate of Ammonia; Ethereal Tinctures, of Tolu, Balsam Peru, Storax, Sweet Gum, Poplar Buds, Benzoin, Matico, St. John's Wort, etc. Or,

the vapor of water containing these articles, either alone, or, in various combinations with each other, may be used. Also, the vapor of aqueous or acetous infusions of Sweet Flag, Wild Carrot, Catnip, Black Cohosh, Gelseminum, Blue Flag, Matico, Stramonium, Parsley Root, Elder Flowers, Golden-rod Leaves, Bloodroot, Agrimony, Sweet Fern, St. John's Wort, Horsetail, (*equisetum hyemale*), Cleavers, Frost Wort, Hyssop, Ground Ivy, etc., as well as vapor of Oil of Cajeput, Oil of Sassafras, Oil of Erigeron, Oil of Rosemary, Oil of Cubebs, Oil of Copaiba, Oil of Cinnamon, etc.,—of the method of combining which, the preceding formulæ will give some idea. I have found these to be even of service in phthisis, to relieve cough and other urgent symptoms. Fifteen drops of Hydriodic Ether, inhaled, at a time, and repeated three or four times a day, have proved useful in chronic bronchitis and the early stage of phthisis. These inhalations are frequently serviceable in removing or lessening bronchial and laryngeal cough, in lessening mucus expectoration, and, in the early period of consumption, to lessen the disposition to tuberculous deposit,—they not only bring the remedies in direct contact with the diseased surfaces of the air-vessels, but accustom the patient to full inspiration and expansion of the chest.

EMPHYSEMA OF THE LUNGS.

There are two different pathological conditions of the lungs to which the term “emphysema” has been applied, and which are usually described as *vesicular emphysema* and *interlobular emphysema*.

Vesicular emphysema consists in dilatation or enlargement of the air-cells, in consequence of which the lungs become enlarged, as well as the chest, and the air in the lungs is augmented in amount. This disease is chronic, and may exist for many years in a mild form; occasionally it manifests itself with a considerable degree of severity, and progresses rapidly. It frequently commences in childhood, and is seldom met with after middle life.

The immediate *causes* of this affection are not satisfactorily understood, though it is known to be a sequel of chronic bronchitis and pneumonia. It has been attributed to a deficiency in the elastic force of the lung, from which its tendency to collapse during respiration is impaired, and, the lungs being more or less constantly expanded by the powerful action of the inspiratory muscles, a permanent enlargement of the air-cells, as well as of the chest, is the result.—On the other hand, it has been stated that expiration is a much more powerful act than inspiration, and that

emphysema may occur from any disease which causes contraction and hypertrophy. Dr. Jenner observes: "The atmospheric air moved by the inspiratory effort can exert comparatively little pressure on the inner surface of the air-cells situated at the extreme margin of the base, the root of the lower lobe (*i. e.* that part immediately next the spine and below the primary bronchus), or at the part of the apex situated in the furrow posterior to the trachea on the right side. While violent expiration, being chiefly performed or greatly aided by the abdominal muscles forcing upward the liver, etc., drives the air (in consequence of the highly arched form of the diaphragm in violent expiration) from the central part of the lung, not only through the bronchi toward the larynx, but also toward the circumference of the lungs, *i. e.*, toward those parts which are the least compressed during expiration."—The disease has followed powerful mental excitement, and sometimes appears as a hereditary malady.

The principal *symptom* in this affection is dyspnœa, which is frequently preceded by cough. At first, the difficulty of breathing, which consists principally in the expiratory effort, or in expelling the air from the lungs, is slight, and may continue so for many years without any change for the worse; or, it may gradually become more and more marked, occurring in paroxysms which threaten suffocation. The respiration is frequently of a loud wheezing character, like that of asthma. As the dilatation of the air-cells obliterates some of the capillary vessels, the circulation of blood through the lungs is more or less interfered with, and the walls of the air-cells become atrophied; hence arises, not only the difficult breathing and sense of constriction, but the general venous congestion as indicated by the bluish, leaden tint of the skin and lips, the peculiar expression of anxiety and melancholy, and the disposition to dilatation and hypertrophy of the heart on its right side, palpitations, and, at a later period of the disease, serous effusions in various parts of the body, and, perhaps, Bright's disease. The nostrils are usually dilated, thickened, and vascular, and the lower lip enlarged.

The chest of such patients has always a rounded appearance on one or both sides, according as one or both sides are affected, the shoulders being more or less elevated and leaning forward, while the patient stoops forward, finding more relief in this position. There can not be said to be, however, a bulging of the intercostal spaces, but rather a wide separation of the ribs. Expectoration is liquid, frothy, and mucous; the muscles of the neck are enlarged; and the strength fails in proportion to the degree of dyspnœa.

The dyspnœa is increased by spasmodic contraction of the bronchial tubes, and by certain seasons and changes of temperature. At an advanced stage, there is a change in the heart's position, which will not be felt beating in the præcordial region, and the movements of the diaphragm will be more or less interfered with. The disease is frequently confounded with asthma, which it very much resembles in some of its symptoms.

Percussion yields an unnatural ringing clearness, somewhat tympanitic, and the sense of resistance to the finger is increased. Auscultation detects a feeble or indistinct vesicular resonance. The inspiratory murmur is diminished both in duration and intensity, while the expiratory is prolonged. If the disease be associated with bronchitis or chronic catarrh, the bronchial rales will be present, dry or moist; usually the dry, crepitant rale attends the prolonged expiration; or, the sibilant rale. (*See Note, page 539, sections 24 and 34.*)

Emphysema may be *discriminated* from *chronic bronchitis*, as the latter is not attended necessarily with an enlargement of the chest, constant feebleness of the vesicular sound, and paroxysms of difficult expiration. From *dilatation of the bronchial tubes*, in which the respiration is bronchial or cavernous, with increased resonance of the voice, and dullness on percussion; and the same may be said of *pneumonia* and *phthisis*, in the latter of which diseases, there is flatness on percussion. From *aneurism*, by the absence of the symptoms of emphysema, and the dullness on percussing over the swelling, its beatings, and its blowing sound. From *chronic pleurisy*, by dullness on percussion directly over the effusion, and an enlargement or prominence at the inferior portion of the chest. From *pneumothorax*, in which the sound elicited on percussion is tympanitic without having the slightest vesicular quality about it, and, over the point where fluid is present, the percussion elicits flatness, as at the lower part of the chest. The respiratory murmur is much more feeble than in emphysema, there is no thrill nor vocal fremitus, and amphoric respiration, metallic tinkling or gutta cadens, and succussion sounds may be present, which is never the case with emphysema. The dyspnœa of pneumothorax is less of an asthmatic character, and its commencement is usually dated as occurring immediately subsequent to a pain in the chest. The history of the two diseases is not alike.

The *prognosis* of vesicular emphysema is not very favorable. Palliation of symptoms is about all that can be effected, especially in advanced cases, for there is no known remedy capable of restoring elasticity to the distended pulmonary membrane, and

still less of diminishing the capacities of the distended or broken-down air-cells. Some writers have affirmed, that, in recent cases, a treatment which will overcome bronchial irritation, may be followed by a return of the vesicular murmur, and a diminution of the volume of the lung; but cures are rarely made.

The *pathological appearances* are an abnormal enlargement of the vesicles of the lungs, which is more especially observed at the free margin of these organs, together with peculiar appendices of various forms, sizes, and structures, resulting from the rupture of the air-cells. The bronchi are seldom involved. When the chest is opened and the lungs are exposed, bladder-like vesicles will be observed in those parts of the lungs affected, and the affected lung or lungs will not collapse, and its substance is apparently more bulky than in the normal state. The upper lobe of the lung is more frequently affected than the lower. Abnormal conditions of the heart and bronchial tubes are sometimes observed as the results of the emphysema.

The *treatment* will be the same as that for brouchitis, with which the emphysema is commonly associated. The dyspnœa may be relieved by half-grain or grain doses of Extract of Cannabis Indica,—by Ether, or Chloroform. Or, antispasmodics may be inhaled with advantage, as, Ethereal Tincture of Lobelia, or, of Stramonium; or, a mixture of equal parts of Stramonium Leaves, Mullein Leaves, Lobelia Leaves, and Sunflower Leaves, (all dried), may be smoked several times a day, or whenever the breathing is troublesome. The more the paroxysms of dyspnœa can be prevented, the greater will be the chances for an ultimate contraction of the dilated air-cells. A pill composed of Strychnia, Extract of Belladonna, and Alcoholic Extract of Aletris, will frequently be found exceedingly beneficial.

The body should be kept warm; the surface of the body, the bowels, and the kidneys be properly attended to; diet must be carefully regulated; exercise must be moderate; and everything must be avoided that will produce mental or physical agitation, or fatigue, or that will irritate the lungs. Change of air frequently affords great relief. If the heart becomes implicated, the conjoined treatment must be in accordance with the cardiac lesion and its symptoms. Much debility will require tonics, as, the Peroxide of Iron, either alone, or in combination with Strychnia, and Alcoholic Extract of Aletris. Chambers recommends the following to be taken in emphysema of the lungs:—Take of Tincture of Chloride of Iron 20 minims, Ethereal Tincture of Lobelia 15 minims, Camphor Mixture one fluidounce,—mix for a dose; to be repeated three times a day.

Interlobular emphysema is the other variety of pulmonary emphysema, and is caused by the rupture of one or more of the air-cells, in consequence of which the air extravasates into the areolar tissue between the cells. It is *caused* by any violent straining efforts, as, lifting heavy weights, excessive laughter, coughing, the bearing-down efforts in parturition, and by obstacles to respiration, as, in bronchitis, pneumonia, whooping-cough, phthisis, etc. In some instances it has caused sudden death, but usually, of itself, the affection is of no vital importance.

The principle *symptom* is the dyspnœa, which is more or less severe according to the extent of the mischief. When the emphysema occurs at the base of the lung, it may enter the mediastinum, and pass from thence into the subcutaneous areolar tissue of other parts of the body, especially under the jaw and in the neck. The physical signs are the same as those belonging to vesicular emphysema, from which it is often very difficult to discriminate it; if its symptoms come on suddenly, immediately after some violent effort, and especially if the emphysematous condition of the cellular tissue of the neck is manifested, there is a strong probability of its being interlobular emphysema,—but the external emphysema may be due to a rupture of the trachea or bronchial vessels. The *pathological characters* consist of an infiltration of air into the cellular tissue between the pulmonary lobules, giving rise to their enlargement, especially toward the surface of the lung or lungs, at which part will be seen air-vesicles or bladders of various sizes and in greater or less numbers; the pressure of the infiltrated air frequently causes a detachment of the pleura. The air-bubbles or bladder are sometimes observed in the course of the vessels passing through the lungs and running over their surface.—The disease is an exceedingly rare one, and though tedious, is seldom of a serious nature. If *treatment* be required, it will be the same as that for vesicular emphysema. The infiltrated air is ultimately absorbed, and the difficult breathing gradually disappears.

PULMONARY APOPLEXY.

This varies from hemoptysis in being a hemorrhage, or effusion of blood into the parenchyma of the lungs. It is by no means a common affection, and usually occurs in individuals who are affected with some cardiac affection, tubercular phthisis with softening, who are of advanced age, etc. It sometimes attacks very suddenly. The *symptoms* are, great difficulty of breathing, some-

times almost to suffocation, oppression of the chest, hurried and unequal thoracic movements, tightness and more or less pain in the chest. The saliva or expectorated mucus is often streaked with a dark, dirty liquorice-looking blood, and which may be expectorated by itself; it has no fetor. When the air-cells are ruptured, an enormous quantity of blood may be expectorated, and then it will be very difficult, if not impossible, to determine the disease from hemoptysis. The pulse is full and frequent, and of a somewhat vibrating character.

Percussion is clear, unless there is considerable extravasation into the lung substance, when it becomes dull. Auscultation will vary the same as percussion; if the latter is clear no change may be observed in the normal respiratory sounds; if dull, in proportion to the degree of dullness, there will be a feeble or suppressed respiration over the part where the extravasation occurs, or, bronchial respiration, bronchophony, and fremitus may be detected, with moist rales, and in case of a cavity, cavernous sounds. (See *Note*, page 539, sections 4, 17, and 18.) In *pneumonia* the difficult breathing increases from the beginning of the malady to its maximum; in pulmonary apoplexy it is more severe at the time of the effusion, and then diminishes. If the expectoration be free from fetor there is no *gangrene* of the lung. In *cancer* of the lung there is more pain, a cough, emaciation, etc.

A *post-mortem examination* shows a dense and dark red appearance of that part of the lung in which the effusion occurs, and which, when cut into, will be found filled with coagulated blood. Rupture of the lung structure may also be noticed. The heart may be affected with hypertrophy of the right ventricle, or, more commonly, obstruction of the mitral orifice.

The *prognosis* is doubtful; the disease often destroys life suddenly; and sometimes by terminating in suppuration and gangrene. When the symptoms are mild, the extravasated blood being enclosed in the air-cells or vesicular structure of the lungs, a recovery may occur.

The *treatment* consists in freely purging the bowels by Croton Oil, or Elaterium, or Blue Flag, etc., and by extensive dry cupping upon the chest. Afterward, counter-irritation to the back, and also to the anterior part of the chest, as well as in the axillary region; together with the internal use of astringents, etc., as, Oil of Turpentine, Warren's Styptic Balsam, Gallic Acid, Tannin, infusion of equal parts of St. John's Wort, Bugle Weed and Beth Root, etc. Oil of Turpentine vapor may also be inhaled, as well as vapor from the infusion just named above. Inhalation of the spray of these infusions,

or of a mixture of Carbolic Acid, Pyroligneous Acid, and Water, will also be of service in some cases. Ice, iced water, acid and astringent fruits, buttermilk, milk, lemonade, and other light, nourishing articles should be prescribed; with other management like that advised under Hemoptysis.

HEMOPTYSIS.

Hemoptysis or Hemorrhage from the Lungs, is generally symptomatic of some serious disorder either of the heart or lungs, more frequently the latter; sometimes, but very rarely, it occurs independent of either cardiac or pulmonary malady, as, from vascular plethora, etc. The blood is hawked or coughed up, and is sometimes so profuse as to prove fatal in two or three days.* The blood most commonly exudes from the capillaries and small arterial ramifications of the mucous membrane of the bronchi, and of the pulmonary parenchyma; it may, however, proceed from an ulcerated or softened blood-vessel. The hemorrhage may occur at any period of life, but is more commonly met with between the ages of eighteen and twenty-five. Sometimes, it will be suddenly manifested in a person not previously supposed to have a tendency to phthisis, and in whom the most careful examination during life, or after death, can not detect any lesion whatever. Frequently, a hemorrhage supposed to be from the lungs, proceeds from the pharynx or larynx, as, in follicular pharyngo-laryngitis, and which is amenable to local treatment.

Hemoptysis may come on without any premonitory *symptoms*, save that of debility, or of peculiar conformation of the thorax. Ordinarily, however, it is preceded by a sense of weight and oppression or pains in the chest, a dry, tickling cough, slight dyspnoea,

*Several years since I was treating a very interesting young lady for tubercular phthisis, and she was apparently improving very rapidly. Her brother, a young man about nineteen, beloved by his family, had never manifested any symptoms of lung disease, except in his formation, having a narrow chest and prominent shoulders, with a stooping forward. He was suddenly attacked with most profuse hemoptysis, which resisted every means to check it, and which proved fatal on the third day. The shock to the sister was so severe that she sank rapidly, and did not survive him for more than eight days. In her case there had never been any hemorrhage. A post-mortem examination of the lungs of the young man revealed an extensive tuberculated condition of them, but no ulceration nor rupture of blood-vessels could be detected; the bronchial membrane was pale and exsanguineous, and portions of the pulmonary tissue was infiltrated with dark blood.

and a hard, jerking pulse ; sometimes, it is preceded by a considerable degree of warmth under the sternum, which shifts around, and very frequently a saltish taste will be experienced shortly before the hemorrhage occurs. At other times, it may be ushered in with shiverings, coldness and weariness of the extremities, pains in the head, back, and loins, costiveness, flatulency, and a rapid, full pulse. Again, it may commence with a tickling sensation at the upper part of the larynx, with an occasional slight hawking or cough,—but when this is the case, the hemorrhage is usually from the larynx.

The amount of blood discharged varies, being sometimes so small as merely to speckle the mucus expectorated, and which is then rarely dangerous, so that it can not properly be termed a “hemoptysis.” At other times, however, it is so profuse as to produce sudden and alarming debility, and even a hasty death ; or, it may come on daily ; at regular or irregular periods ; may continue unceasingly for many days together ; or, it may happen only once or twice during a life-time. Occasionally, it flows so abundantly as to be ejected through the nostrils as well as through the mouth. In some instances the slightest exertion of the voice, or of the body, or even a powerful mental excitement, will occasion a return of the bleeding ; but as often it returns without any such cause. The blood is thin, florid-red, and frothy, but when very abundant, and especially after the first attack, it is not so apt to be frothy ; sometimes, especially after one or more bleedings have already happened, it is thick, and of a dark or blackish cast, the result of its retention for a longer or shorter time in the air-passages previous to its being coughed up. In a few cases, the blood will have more of a venous than an arterial appearance from the commencement. The pulse becomes quick, full, and bounding, prostration occurs more or less rapidly in proportion to the quantity of blood lost, the skin has a cold dampness upon it, and the patient becomes greatly alarmed and anxious. The face is sometimes alternately flushed and pale ; there may be palpitation ; and when the blood is effused into the bronchial divisions, the patient experiences a distressing sense of ebullition in the chest. According to the quantity of the hemorrhage, and the disease of which it may be symptomatic, will be the general symptoms.

As already remarked, in the great majority of instances, hemoptysis is symptomatic of other diseases, especially tubercular phthisis, usually manifesting itself as one of the early symptoms of this malady, though not always present, and frequently disappearing for a long period previous to the fatal termination. “The obliteration of

the minuter twigs of the pulmonary artery speedily follows the deposition of tubercles; for when an injection is thrown into the pulmonary artery, it rarely happens that it can be propelled into the immediate vicinity of the crude tubercles.”—“Closure of the pulmonary arteries takes place here precisely as in the instance of the foetal vessels and of phlebitis; although without there being any ground for our assuming vascular inflammation. The walls of these vessels thicken or swell quite disproportionately; the several tunics merge into a single uniform sero-lardaceous mass; and the calibre, which long continues narrow, though pervious, becomes eventually filled with a thin, reddish, fibrinous plug, transforming the whole vessel into a solid cord. These cords either form a coarse network covered with remnants of lung, and invested with a purulent crust, upon the walls of a cavity, or traverse the latter as bands or bridles. In rare instances, a cord of this description tears, through attenuation, midway between its two ends, before definitive closure of its calibre. Then ensues more or less violent hemorrhage, which often proves suddenly fatal; the vomica and the bronchial tubes corresponding are found replete with coagulated blood, which probably fills in a frothy state the trachea and larynx.

“The above explanation of the deportment of the blood-vessels will, at once, account for the hemorrhage so frequently attendant on tubercular disease. It is often considerable at the outset, and recurs from time to time during the progress of phthisis, although not to such an amount as immediately to threaten life. It is chiefly observed where tubercle is rapidly developed in connection with inflammatory action, or where the pulmonary texture is replete with densely-clustered tubercles. Carswell is, upon the whole, right in stating that the blood is poured out, because the pulmonary veins, being compressed by the multitude of tubercles, are not in a condition to take up the whole of the arterial supply.” (*Hasse*.) Hence we may observe from this statement, that while the actual rupture of a large vessel traversing a vomica, may, occasionally, give rise to a bleeding from the lungs, it is much more frequently due to an exhalation from obstructed capillaries.

Other *causes* which impede the return of blood from the lungs, ultimately producing a congested condition of their blood-vessels, giving rise to a sanguineous exhalation from the capillaries of these organs, are, diseases of the aortic or mitral valves, compression of the pulmonary veins by tumors, aneurisms, etc. A profuse and fatal hemorrhage may follow the rupture of an aneurism into the bronchi; and hemorrhage will occasionally manifest itself in pulmonary apoplexy. Hemoptysis may also occur from a local or gen-

eral plethoric condition, due to a retention of customary evacuations, and more especially when the retention is a consequence of some tubercular formation; it may also be manifested without any known cause.

The exciting causes of bleeding from the lungs or bronchial vessels, are, violent exercise; injuries to the chest; severe straining; improper exercise of the lungs in singing, speaking, blowing on wind-instruments, etc.; a diminution of the weight of the atmosphere, as a sudden removal from a denser to a rarer atmosphere; inhalation of irritating particles, etc. Ordinarily, it is not immediately dangerous, though nearly always indicative of a serious malady, and in such instances, those who are strongly predisposed to it, present some faulty confirmation, as, narrow chests, round shoulders, and often signs of phthisis, as, cough, thoracic pains, dyspnœa, etc.—A hemoptysis often occurs toward the termination of pneumonia, pleurisy, small-pox, and some fevers, and if not too profuse, is a favorable indication.—After the hemorrhage has ceased, we should always endeavor to ascertain by percussion, auscultation, etc., whether it depends upon disease of the lungs, or heart, or upon some other condition.

In the *diagnosis* of hemoptysis, we must remember that the blood is at first of a bright, florid character, frothy, is hawked or coughed up, and its appearance is generally preceded by an uneasiness and oppressed sensation in the chest, a sweetish or salty taste, and a sense of tickling in the larynx. After a few attacks of bleeding, it may contain dark clots. In *epistaxis* the blood is never florid and frothy, although it may be coughed or hawked up, is not accompanied with the quick, full, bounding pulse, the cold sweats, great anxiety, and chest symptoms of hemoptysis; and upon stooping forward it will flow from the nostril. In *hematemesis* the blood is dark, thick, and often mixed with the contents of the stomach; it is generally vomited up without either coughing or hawking, and some blood may frequently be observed in the stools. Weight, uneasiness, and tenderness of the epigastric region is ordinarily present, and sometimes nausea. When a *large blood-vessel* or an *aneurism* ruptures, the blood is of an arterial character, is profusely discharged by jets, and speedily terminates fatally. When bleeding proceeds from the *larynx*, *trachea*, or *œsophagus*, which is of rare occurrence, it is seldom profuse, is unaccompanied by any of the local sensations in the chest or stomach, above described, and in many instances, its seat may be recognized by the laryngoscope.

The *pathological appearances* are, a more or less red, livid, and tumefied condition of the bronchial membrane, or, it may be pale

or, softened and tinged with red, or, no symptoms of a pathological state may be observed. A congested or inflammatory appearance of portions of the lungs may also be noticed, their substance being infiltrated with blood; and, if any lesion of the lungs, heart, or large vessels are associated with the hemorrhage, the appearances peculiar to such lesion will also be found present.

The *prognosis* of hemoptysis when profuse is unfavorable; when not so profuse, it is favorable as far as the hemorrhage itself is concerned, but not so far as relates to the disease of which it is symptomatic. If this be of the heart or lungs, the prognosis is more or less unfavorable as to a permanent recovery. If the bleeding be due to a congested condition of the pulmonary organs, from suppressed evacuations, etc., the prognosis is favorable, provided the suppression be not a consequence of pulmonary, cardiac, or tubercular disease.

In the *treatment* of hemoptysis the practitioner should be calm and collected, and pursue his measures with promptness and decision. The patient should be immediately placed in a semi-recumbent position, having the room cool, and well ventilated, and allowing but few persons to be present; in warm weather he may be fanned, or the fresh air may be permitted to blow upon his chest. The most perfect quiet must be enjoined, prohibiting him from talking, and requesting him to suppress cough as much as possible. Warmth and stimulation must be applied, as soon as can be done, to the feet and lower legs, and some Turpentine Liniment may be rubbed upon the chest and back until it produces a glow of warmth, or, burning sensation; and, if the hemorrhage be very profuse and alarming, ligatures should be applied around the thighs and upper part of the arms, near the body, being careful not to tighten them so as to interfere with the circulation of the arteries; and, after the discharge has become arrested, the ligatures may be gradually loosened and removed.

Sometimes, the practitioner may not have the remedy he desires to use, immediately at hand, when he should promptly administer half a teaspoonful of common Salt, or of Oil of Turpentine, repeating the dose every twenty or thirty minutes, according to the urgency of the case, and continuing it, until the bleeding is checked, or until he has received the remedy sent for.

The Tincture of *Veratrum Viride*, two or three drops every half hour, until it has lessened the rapidity and bounding character of the pulse, will be found a most useful agent, in conjunction with Gallic Acid, in twenty or thirty grain doses every one, two, or four hours according to the urgency of the case. In some instances, a

powder, consisting of Capsicum five grains, Ipecacuanha one or two grains, and Opium half a grain, may be given, every half-hour, hour, or two hours, as may be required; it will be found useful especially where there is much uneasiness and restlessness; this preparation will also be found useful in preventing increased capillary congestion of the bronchi or lungs, or an infiltration of the effused blood into them, which are so apt to follow the hemorrhage, from greater or less impairment of the vital tone of these organs. If nausea result from the Ipecacuanha in this powder, it often induces a sedation that will reduce the vascular action. A mixture composed of Tincture of Chloride of Iron one fluidrachm and a half, Chlorate of Potassa two drachms, Water six fluidounces, has frequently checked the bleeding promptly when given in teaspoonful doses repeated every two or three hours. Inhalation of spray of Diluted Carbolic Acid, or, of solution of Perchloride of Iron, has likewise been successful.

Other agents have been employed with advantage, to lessen arterial action, as, the Tinctures of Aconite, Sheep Laurel, Digitalis, etc. Also to check the hemorrhage, as, Oil of Fleabane, Oil of Fireweed, Warren's Styptic Balsam, Tincture of Matico, or, half fluidrachm doses of a mixture of equal parts of Tincture of Cinnamon, Tincture of Rhatany, and Oil of Turpentine—repeating the dose as may be required. *Lycopus Virginicus* in infusion, or wineglassful doses of a decoction of equal parts of Black Cohosh, Beth Root, and *Lycopus*, will also be found useful in those cases where the hemorrhage is persistent; these drinks may also be employed in conjunction with the other remedies employed.

If the hemorrhage occurs in a patient of full habit, much benefit will be derived from an active cathartic, given after the cessation of the discharge, or upon its decline—saline cathartics are the best, as a combination of four drachms of Cream of Tartar, and three drachms of Sulphate of Magnesia, taken in three or four fluidounces of Spearmint Water, or in infusion of Matico, Buchu, Cleavers, etc. If cough be present, some slightly nauseating cough mixture may be prescribed, as, a combination of Tincture of Bloodroot, Syrup of Ipecacuanha, Syrup of Tolu, each, equal parts, to be given in fluidrachm doses, each dose containing one-eighth, or one-sixth of a grain of Sulphate of Morphia. Should a sense of oppression remain in the chest, after the hemorrhage has been checked for some time, with crepitation diffused through one or both lungs, it is generally due to irritation from blood accumulated in the bronchi, and will require for its removal, the cautious employment of a prompt emetic.—Professor Morton, of Philadelphia,

states that the retching and vomiting of sea-sickness does not increase, nor cause a return of, the hemoptysis symptomatic of tubercular consumption.—Sometimes, in the milder forms of hemorrhage, or toward the decline of a profuse bleeding, inhalations of warm vapors will be useful, as, of Diluted Acetic Acid, Oil of Turpentine, Benzoic Acid, or, a combination of Oil of Erigeron one fluidrachm, Oil of Turpentine two fluidrachms, Tincture of Stramonium half a fluidounce.—After the cessation of the hemoptysis, means should be taken to cure or suspend the progress of the malady of which it is symptomatic; and if this can not be done, we must prepare the patient for a return of the bleeding, having him to keep all the necessary remedies near at hand, at the same time keeping his system constantly under the influence of one of the astringent remedies or decoctions already named. Sometimes, the hemoptysis appears periodically, in which case one of the salts of Quinia will be found useful.

Patients of an enfeebled, anemic condition, who are attacked with bleeding from the lungs, should use a mild nourishing diet, consisting chiefly of milk, eggs, oysters, gruel, panada, strong beef tea, etc.; and in passive bleedings three or four grains of Sulphate of Iron, Perchloride of Iron, Iodide of Iron, or other ferruginous preparation, should be taken daily; being very careful, however, not to use iron in active hemorrhages, as it will increase the difficulty. Passive exercise should be taken in the open air, together with very moderate and properly regulated physical exercise to expand the thorax and give tone and development to its contained organs.—Those of full habit should confine themselves, for some time, to a bread and milk diet, with soups, broths, and beef tea used sparingly, and boiled green corn during its season; they should avoid all solid animal food, tea, coffee, all liquors, indigestible, flatulent, and stimulating articles. Oranges, lemons, ripe acid fruits are very proper, and all drinks should be taken cold.—Where persons are disposed to hemoptysis, they should have their bowels kept regular, their digestive organs in a normal condition, and their skin clean and warm; they should not be allowed to sing, talk long or loud, or blow upon wind-instruments, and should avoid elevated, cold situations, preferring a flat or low country where the air is dense, and comfortably warm and dry. Sexual indulgence must also be prohibited in severe cases.

PNEUMOTHORAX.

When air or gas is contained in the pleural cavity, it is termed *pneumothorax*; when, in addition, there is liquid present as well as air, it is termed *pneumothorax with effusion*, or *pneumohydrothorax*. The latter condition is more commonly met with than the former; both affections will be considered under the present caption.

The *symptoms* are generally observed at first, either during or after a fit of coughing, which occasions a rupture and allows air to pass from the lung into the pleural cavity; they are, intense pain; great oppression of the chest; rapid and extreme dyspnœa, according to the rapidity and amount of the effusion, frequently threatening suffocation; usually palpitation of the heart; and a manifestation of great anxiety, pallor, faintness, feebleness, and a rapid, feeble pulse. The patient generally remains in a sitting posture, or, if he lies down, it is invariably on the side affected, as he can not rest an instant on the healthy side. If the accident does not prove immediately fatal, acute pleuritis soon follows, with effusion of fluid. It is only, however, by the physical signs, that we can correctly and positively diagnose this lesion.

The affected side is often more prominent than the other, and percussion yields an unusual degree of clearness or resonance, which is of a decided tympanitic character, and no thrill or fremitus will be felt; if the examination be made while the patient is in a sitting posture, the clear, tympanitic sound will be developed over the upper portion of the chest, while below, it may be dull, or flat, from the presence of fluid. Auscultation detects the respiratory sound feeble, indistinct, or suppressed; amphoric resonance, metallic tinkling, and gutta cadens, may also be present. Succussion will detect a splashing sound when there is fluid as well as air in the pleural cavity. (*See Note, page 539, sections 33 and 35.*)

When, during a paroxysm of cough, or directly after, a patient laboring under tubercular phthisis is suddenly attacked in one side of the chest with the symptoms heretofore named, we have true grounds for suspecting perforation of the lung; and our suspicions will be confirmed by a careful examination of the chest by percussion and auscultation. There are, however, some exceptions to this general rule. In some respects the lesion resembles Emphysema of the Lungs, but may be determined from it by the means named under that affection.

The most common *cause* of pneumothorax is a rupture or perforation of the lung, admitting the entrance of air from without

into the cavity of the pleura, giving rise to a compression or collapsed condition of the lung, sometimes forcing it toward or against the spinal column. The perforation is associated mostly with a tuberculous state of the lung, as, an excavation; but it may happen from the formation of an abscess, the result of pneumonia; from gangrene of the lung involving the pleura; from cancer of the lung; from rupture of an enlarged bronchial tube; or of a dilated air-cell; or, from any cause that forms a free passage between the pleural cavity and the bronchi. Sometimes it may occur from perforation of the pleura by wounds; and, very rarely, gas may be exhaled spontaneously from the pleura. The lesion occurs much more frequently in the left lung and pleura, and is most common among those who are disposed to tubercula of the lungs. Occasionally it is met with on both sides.

The *pathological appearances* are those of the tuberculous or other disease associated with the pneumothorax, together with one or more lung (or pleural) perforations of various sizes, in most cases situated near the angles of the third or fourth ribs, and which form a channel of communication between the pleural and the pulmonary cavities. Air will also be observed in the former cavity, and, in the majority of cases, more or less purulent or sero-purulent fluid, which, as well as the air, may or may not be fetid.

When the lesion is associated with tuberculous disease of the lung, and especially in the advanced stage of it, the *prognosis* is unfavorable; in the earlier stage, life may be prolonged for several months. The disease has, in a few instances, existed for five or six years before death occurred. A favorable termination by absorption happens very rarely. More frequently, after pneumothorax has been established, the patient will survive but a few months.

The *treatment* of pneumothorax will be based upon the circumstances occasioning it, being wholly of a palliative character. If it be the result of a perforation from lung disease, occasioning great moral and physical depression at the time of its occurrence, stimulant and restorative measures will be required. If the patient recovers from the immediate influence of the lesion, and symptoms of irritation or inflammation are manifested, these must be met by the ordinary means for such conditions, treating them upon general principles according to the indications; counter-irritants, as, dry cupping over the whole chest will often prove useful. The dyspnoea may often be relieved by the administration of Extract of Cannabis, Stramonium, or Belladonna, Tincture of Aconite, Solution of Morphia, etc. At any time when there is great distress and dyspnoea, and reasonable fears are entertained of suffocation within a

short period, the operation of paracentesis thoracis should be performed, which, if it will not cure, will afford great relief, and aid in lessening the immediate risk of life; indeed, the operation may, in some cases, be repeated several times without incurring any danger, when properly performed. The general treatment will be that proper for the pleural or pulmonary malady, whatever that may be,—more commonly tuberculosis of the lungs.

ASTHMA.

Asthma or Phthisic is a peculiar morbid irritable condition of the nervous system, which, when exposed to certain ordinary influences not affecting the majority of mankind, gives rise to a spasmodic condition of the bronchial muscles, accompanied with a temporary difficulty of breathing, a wheezing sound, and a sense of tightness across the chest. Pure uncomplicated asthma is rarely met with, and is more common in women, while asthma, complicated with bronchitis or heart disease, is more common in men than women, in the proportion of ten to one. The disease may appear at any period of life from infancy to old age, being, however, in advanced life almost always complicated with pulmonary or cardiac disease. In childhood it is more generally due to a sensitive bronchial mucous membrane, resulting from whooping-cough, bronchitis, or measles, (and sometimes to emphysema, and pulmonary collapse), in a constitution somewhat disposed to the disease; and those cases that are perfectly pure and uncomplicated are ordinarily met with between the ages of fifteen and twenty-five. Asthma is a very capricious disease, being, with some patients, developed by causes which cure it in others; being cured by one agent in certain instances, which is perfectly worthless in others, and, frequently, one remedy which removes the paroxysm, for a time or two, of a patient, is forever after of no benefit to him. Again, the disease may, with some, be preceded by certain premonitory symptoms, while, in others, its attacks are sudden and unexpected; or, it may occur at regular or irregular periods, or, without any trace of periodicity whatever; with some the disease is manifested only during the warm seasons, while with others there is a more or less complete exemption from it during warm weather. And in various other ways, as, to its causes, the character of its paroxysms, its behavior under the influence of remedies, etc., does it exhibit its contrariety and capriciousness, being, in these respects, equalled only by hysteria. Death from asthma is exceedingly rare; indeed, it is doubtful whether it ever happens; but when the malady is associated with certain pulmonary

or cardiac lesions, occurring idiopathically, or, as a consequence of the asthma, then a fatal termination frequently occurs.

Precursory *symptoms* are frequently present, so that most asthmatics are fully aware that a paroxysm is coming on; these premonitory signs vary with different patients, both with regard to the time at which they appear, and their nature. They may be experienced only an hour or two previous to the attack, on the preceding night, or, for several days prior. They are, as it were, the commencement of that particular nervous condition which culminates in, or is more completely developed by, the subsequent respiratory phenomena; they are, a sense of fullness in the epigastric region; drowsiness; lassitude; heaviness; headache; flatulency; nausea; diuresis and pale urine; itching sensations, especially under the chin, between the shoulders, and over the sternum; and disturbed rest. With some, there is an unusual mental activity, buoyancy of spirits, and wakefulness; with others, attacks, apparently but not really catarrhal, will be developed; and again, the paroxysm may come on suddenly, without any warnings, and most generally during the night. In most instances it comes on early in the morning, or, when the patient awakes during the night; it may, however, occur at any hour of the day or night. Not unfrequently, the attack will be preceded by neuralgic pains in the testes, the tibia, or in other parts.

As the respiratory phenomena become developed, the breathing becomes more and more distressed and difficult, a sense of tightness across the chest is experienced, and the respiration becomes of a wheezing character; the speech becomes uneasy and difficult, and there is a tendency to cough. The itching comes on as soon as the tightness of breathing is first felt, it is incessant, is not relieved by scratching, and disappears as soon as the paroxysm has reached its height,—however, it is not present in all cases. These phenomena progress more or less rapidly, becoming more and more alarming in their character, and threatening suffocation. The patient is compelled to start up from a horizontal position, and seek a window or door for fresh air, or he may sit immovably in a chair, unable to speak, or even to move his head. The breathing is slow and difficult, more of a gasping character, expiration being much longer than the inspiration, the difficulty being to get the air out of the chest, and which is ultimately affected by a sudden expiratory jerk, and the moment expiration is completed the inspiration begins—there is no pause, the normal post-expiratory rest is lost. At every breath the head is thrown back; the shoulders more and more raised; the head, being, as it were, buried between them; the back

is rounded; the gait stooping; the mouth a little open; the face expressive of the intensest anxiety and distress; the eyes wide open, often strained, turgid, and suffused; the face purplish and distended, or very pale and collapsed; with a cold perspiration oozing from the forehead, and the surface of the body; and the muscles of respiration rigid and tightened like cords, and tugging and straining for every breath that is drawn. The tongue is usually coated; flatulency and constipation are by no means uncommon; the pulse is generally small and feeble, though it may be regular, irregular, slow, or rapid; the urine is abundant, pale, and inodorous, but becomes high-colored, less in quantity, and deposits a sediment on cooling, at the close of the paroxysm. The chest becomes enlarged in every direction during the paroxysm, the abdomen also becomes distended, and as soon as the attack disappears, both the chest and abdomen return to their original size.—The symptoms named continue for a longer or shorter period, from a few minutes to one or two days; but usually, when they occur in the night, they gradually decline on the approach of morning, the breathing becomes freer, coughing and speaking is less difficult, more or less expectoration ensues, much relief is experienced, and the patient usually falls asleep.

The paroxysm may end for the time, in symptoms of decided and more or less prolonged relief, or, it may only be a remission; in the latter case, a sense of tightness across the chest, slight difficulty of breathing, uneasiness on motion, and an inability to remain in the recumbent position, will continue in a slight degree through the succeeding day; on the approach of night, drowsiness, flatulency, difficulty of breathing, and the other symptoms will gradually come on, until they become as violent as on the preceding night. And the paroxysms and remissions may continue in this manner for several successive days, leaving the patient in an exhausted condition, with a slight feeling of tightness across the chest, and considerable tenderness of the muscles on motion.

When a paroxysm of asthma has once happened it is very apt to return at various regular or uncertain periods; sometimes every year or two, at others upon every appreciable variation in the condition of the atmosphere, or, upon every exposure to its exciting cause; and, again, it may recur daily, or every week or two, more especially when complicated with some lung or heart disease. If the disease has existed for a long time, it changes its type, does not produce so much suffering as in former years, but the patient is constantly troubled with more or less difficulty and wheezing of respiration, and these changes are due to the decrease of nervous

irritability and tendency to spasm as life advances, to a gradual loss of reparative power in the lungs, and to an accumulated disorganization or disease of the lungs or heart, from the continued operation of its cause. If the asthma is severe and happens frequently, it soon produces a pulmonary lesion.

Percussion, during a paroxysm, yields an unusual clearness of sound. Auscultation will hardly, if at all, detect the normal vesicular resonance, which is generally replaced by the dry sounds, large and small,—sonorous and sibilant of every variety, note, and pitch. They may be heard in all parts of the chest, high and shrill, whistling, cooing, squeaking, snoring, etc., all occurring simultaneously, or alternately,—and these sounds will frequently vary in the same part. Toward the termination of the paroxysm, if expectoration is about to take place, the moist or bubbling sounds may be observed.

The *cause* of asthma is a peculiar morbid irritability of the nervous system,—or, a morbid sensitiveness of the pulmonary nervous system,—which may be the result of a previous disease, as, pertussis, measles, bronchitis, etc., abnormally influencing the bronchial mucous membrane; which may exist primarily, perhaps from some organic peculiarity of the lungs; or, which may be inherited. When this irritability is aroused by the exciting causes, a spastic contraction of the fiber-cells of the organic or unstriped muscle of the bronchial tubes is produced, their calibre is diminished or narrowed,—a spasmodic bronchial stricture is the result, preventing a free and full expiration, and giving rise to all the attendant asthmatic phenomena. And, in the majority of instances, these phenomena are those of reflex action.

The exciting causes of a paroxysm of asthma are numerous and varied; thus it may be developed by a cold moist atmosphere; sudden changes of temperature; noxious or irritating vapors; dusty or smoky atmosphere; violent mental emotions; suppression of customary evacuations; constipation; irritating or indigestible articles of diet; hearty suppers; full meals; certain peculiar kinds of food; slight but sudden nervous shocks; an unhealthy condition of the blood: a perverted condition of nervous sensitiveness or irritability; use of malt, vinous, or alcoholic drinks; masturbation; sexual indulgence; overexercise, etc. With certain persons an attack of asthma is induced only by certain odors or vapors, as, of ammonia, tobacco smoke, smoke of burning pitch, the effluvium of hay, or of ipecacuanha, or of certain grasses, etc.; with some, the peculiar irritation is never induced except by the action of the one sole cause, as, in the hay or ipecac-asthma; with others, it may

be aroused by any irritant, whenever exposed to its influence. Occasionally the peculiar asthmatic nervous irritability may be produced by metastasis of rheumatism or gout, dyspepsia, frequent catarrhal attacks, scrofulous taint, enlarged liver, aneurisms, tumors, etc. The malady may also be hereditary, and is almost always associated with some faulty conformation of the chest, either as an original, or a secondary condition.

Asthma is termed *intrinsic*, when the exciting cause is applied directly to the lungs; *reflex*, when the source of irritation has a distant seat, as, in the stomach, bowels, uterus, or other peripheral seat; *central*, when from sudden emotion; *organic*, when complicating bronchitis, heart disease, etc.

Asthma is frequently confounded with the dyspnœa of bronchitis, of emphysema, and of heart disease, and it is of importance to *discriminate* between them. Asthma is always preceded by an intolerable sense of want of breath; is free from cough, or if cough is present, it is dry; the breathing is tight, long drawn, laboring, and wheezing; the expiration is much more prolonged than in dyspnœa from emphysema, bronchitis, phthisis, or heart disease; there is no post-expiratory rest; and the almost motionless expiration, which is three, four, or five times longer than the inspiration, is often terminated by a sudden expiratory jerk, which empties out the balance of air remaining in the lungs, and is immediately followed by inspiration. An examination of the expectoration at the close of an asthmatic paroxysm, under the microscope, will detect a homogeneous viscid matter, containing innumerable corpuscles, about $\frac{1}{1500}$ th of an inch in diameter, some of which are oval, others oblong, fusiform, caudate, and sub-linear, having the same refracting power, pale, homogeneous, or almost nebular, and apparently devoid of cell-walls. Also larger spherical or oval cells, from $\frac{1}{500}$ th to $\frac{1}{800}$ th of an inch in diameter, mostly in groups, coarsely granular, and filled with particles of black carbonaceous matter when the patient breathes a smoky atmosphere, but pale, finely granular, and not opaque when this is not the case. Sometimes more or less blood will be present, in some instances amounting to a hemorrhage.

The dyspnœa of *bronchitis* is not paroxysmal, is short, crepitous, and accompanied with cough, and is not wheezing. In pure *emphysema* the dyspnœa is constant, varies but little, and is not wheezing. The dyspnœa of *heart disease* is intolerant of the least exertion, or of the recumbent position, and sitting up, or stillness, may cure the most violent paroxysm in a few minutes, it is more of an orthopnœa than a dyspnœa, the breathing is not labored and

wheezing, but more of a panting and gasping character. The dyspnœa of *anemia*, or of *chlorosis*, is a form of panting breathlessness like that following overexercise in a state of health, it is not wheezing, and is not accompanied by any cardiac or pulmonary signs to explain it, and is probably due to a proper want of oxygenization of the blood owing to its deficiency of red globules. Yet, it must be recollected, however, that we may have a considerable amount of genuine asthma with chronic bronchitis, emphysema, cardiac disease, etc., but then the symptoms of these affections remain after the paroxysm of asthma has passed away. Besides which, the asthmatic attacks, as a general rule, are very rare or very mild when the affection is uncomplicated, but are more severe, and persistent, and occur much more frequently, when it is complicated with lung or heart disease.

A hypertrophy and thickening of the circular fibers of the bronchi, with a diminution of their calibre, giving rise to a constant difficulty of breathing, of greater or less severity, has been observed in asthma, but this is undoubtedly of inflammatory origin. Dilatation of the bronchial tubes is due to bronchitis and not to asthma. The consequences of asthma are really as follows; engorgement of the pulmonary vessels, perhaps, thickening of the walls of the ultimate arterial twigs; loss of tone of the vessels; œdema of the lungs; emphysema of the lungs, which is the most common morbid change observed; and hypertrophy and dilatation of the right side of the heart. The face of an asthmatic becomes thin, pale or dusky, and has rather an anxious expression; the cheeks are hollow; the lines of the face deeply marked; the mouth usually open, and the jaw rather hanging; the eyes are generally prominent, turgid, and watery, more especially when there is cardiac dilatation; the back is rounding; the shoulders high and stooping forward, with the head thrown back; the chest *pigeon-breasted*; the body does not move in walking, the limbs alone move, somewhat awkwardly, as it were; the voice is peculiar, feeble and somewhat hoarse and rough, and, as if the person were tired or out of breath; and a single dry cough is usually present. These appearances and conditions are generally absent in uncomplicated asthma, but are always present in a greater or less degree when lung or heart disease is present, and in proportion to the extent, duration, and character of the complication.

The *prognosis* of uncomplicated asthma, especially in early life, is favorable, but after the fortieth year very few cures are effected. Indeed, it is rarely the case that asthma exists at this period of life without being associated with some lung or cardiac disease that renders it incurable. Children generally outgrow the disease under

proper management, provided there exists no incurable lesion of the lungs or heart; and in adult life and middle age, a cure is possible under similar circumstances. Complications, particularly in advanced years, render asthma absolutely incurable. The longer the period of each paroxysm the greater is the danger of injury to the lungs, and the less favorable is the prognosis. Paroxysms frequently repeated, also tend to produce abnormal conditions of the heart and lungs, and have an unfavorable signification. If the completeness of the recovery between the attacks is perfect, the breathing being free, without any shortness or difficulty whatever, it is favorable, as indicating that the paroxysm has left no permanent morbid influence upon the pulmonary circulation. The right side of the heart rarely becomes dilated by asthma, however severe the dyspnoea may be during the paroxysms, if the intervals between them are considerable, and the recovery in those intervals complete. A continued chronic cough or expectoration, or both co-existing, is a bad sign in asthma, signifying that the asthma is complicated with bronchial inflammation or congestion,—this state has been called “humid asthma.” If the asthmatic phenomena appear to be gradually improving, instead of becoming more intense, the attacks being of less severity and less frequent, this is a favorable omen. In many cases the prognosis is determined by the character of the exciting cause of the asthma, especially when this is single, and can be detected; if we can remove or prevent it, the asthma may be cured; if not, the paroxysms will continue to return whenever this cause is present. In all cases, but little encouragement should be given, when the asthma is connected with, or is dependent upon, disease of the heart, lungs, or other vital organs. When the breathing becomes suddenly quick and short, the pulse weak and irregular, with paralysis of the arms, great prostration of strength, scanty urine, and frothing at the mouth, the danger is imminent.

There are no *pathological appearances* peculiar to asthma; those of its complications, when they exist, will alone be observed.

The *treatment* of asthma consists, firstly, in arresting or mitigating the paroxysm; and secondly, in adopting measures during its absence to prevent its return. During the paroxysm one of the most valuable remedies in affording prompt relief is the Compound Tincture of Lobelia and Capsicum, which may be given in nauseating doses, from two to four fluidrachms, every ten, fifteen or twenty minutes. But, in many cases, the practitioner will ascertain that the exciting cause lies in some derangement of the digestive organs, as a full meal, some irritating or indigestible diet, or a constipated condition of the bowels; in these cases, as well as in those

where the exciting cause can not be learned, and there are no contraindications present, an emetic should be given to relieve the irritation at the stomach, as, the Compound Powder of Lobelia, or the Acetated Tincture of Bloodroot. The existence of heart disease would contraindicate the use of an emetic or nauseant.—And to unload the rectum, a purgative enema should be administered, to which is added half a fluidounce, or a fluidounce of the Compound Tincture of Lobelia. After these agents have operated, should the paroxysm still continue, relaxation of the spasm may be effected by the internal exhibition of the Compound Tincture of Lobelia and Capsicum, as named above. In conjunction with these measures, the throat, neck, and upper portions of the chest and back should be bathed with the Compound Liniment of Oil of Amber, especially in severe cases; applying it with considerable friction, and repeating it two or three times in as many hours. The best position for the patient is, to sit or stand in front of a table of convenient height, with a pillow on it, upon which he may rest his elbows, and throw himself forward.

The inhalation of Chloroform is another prompt and efficient agent to check the asthmatic paroxysm, especially in the uncomplicated form; a few whiffs will relieve the breathing, and it is seldom required to produce insensibility before the spasm yields and the breathing becomes free. It should be administered at as early a period as possible,—at the very commencement of the attack. Nitrous Ether has also been advised as an inhalent.

Among the agents that have been found useful in asthma, to relieve the paroxysm, are, the following:

1. A cupful of clear strong coffee, every half hour or hour; its influence will often gradually wear out and, in some cases, it will develop an attack.

2. Take of Lobelia one pound, Alcohol, Spirit of Nitrous Ether, each, four pints, Sulphuric Ether four fluidrachms; mix, and form a tincture, of which the dose is a fluidrachm or two as often as required. This tincture should be kept perfectly excluded from light.

3. Saturate thin unglazed white paper with a saturated solution of Nitre, and carefully dry it. To use it, ignite one end, and let it burn in a close room in which the patient is seated, so that he can inhale its fumes. One pound of Nitre furnishes, when heated to redness, four hundred pints of oxygen gas.—Nitrate of Ammonia may be similarly employed.

4. Take of pasteboard four ounces; break it down with hot water and form a paste, which should be thoroughly mixed with

Nitre, two ounces, Belladonna, Stramonium, Lobelia, each, in powder, twenty grains, powdered Myrrh, Olibanum, each, two and a half drachms. When mixed, roll into sheets, and cut into small squares,—to be burned in small saucers, the same as the preceding.

5. Take of Sunflower Leaves, Stramonium Leaves, Mullein Leaves, each, one ounce, add to them one ounce of very finely-powdered Nitre, half an ounce of Lobelia Leaves, and two drachms of Benzoic Acid. This may be smoked in a pipe, and will be found of decided advantage in many instances.

6. Touch the fauces and back parts of the throat with a mixture of one part of strong Aqua Ammonia, and six or eight parts of Water.

If the paroxysm be owing to checked perspiration, or to rheumatic metastasis, diaphoresis should be produced as soon as possible, by placing the feet of the patient in hot water, and administering the Compound Tincture of Virginia Snakeroot, every fifteen or thirty minutes, in doses of one or two fluidrachms. And in rheumatic metastasis, additional measures may also be pursued, as, Dry Cupping, or Firing along the spinal column.

Indeed, in all cases, it should be the object of the practitioner to ascertain the exciting cause of the asthma, that he may promptly put into requisition the proper measures to have it removed, avoided, or placed under control. An avoidance or removal of the cause, whether it be residing in a certain locality, the inhalation of certain vapors or odors, the use of certain articles of diet, or, hearty suppers, gastric irritation, constipation, etc., will almost invariably be followed by a permanent cure, or at least by no farther paroxysms as long as the patient remains unexposed to the influence of the exciting cause, whatever this may be. And it will often be the case, that the exposure of a patient to a certain cause will induce an attack, while with another person, the same cause will promptly relieve the asthmatic paroxysm whenever it comes on,—of such a capricious character is the disease.

In the intervals between the paroxysms, treatment must be pursued to effect a radical cure; but we must frequently expect to meet with disappointment. If any complication exists, in addition to the measures pursued to cure the asthma, we must also adopt an appropriate treatment for the cure of the complication; the complication cured permits the asthma to be cured; its relief, lessens the intensity of the asthmatic attack; its persistence, renders the asthma absolutely incurable.

In uncomplicated asthma, to lessen the peculiar irritability of

the pulmonary nervous system, and lessen the disposition to spasm of the bronchial muscles, I have found the following measures to be very valuable: Take of Lobelia Seed, Skunk Cabbage Balls, Mullein Root and Seed, each, one ounce; High Cranberry Bark two ounces; Stramonium Seed, Capsicum, each, half an ounce; Alcohol five pints; mix, and form a tincture. Of this preparation, give from twenty to sixty minims for a dose, repeating it three times every day. Likewise administer the following pills: Take of Sulphate of Quinia half a drachm, Flowers of Sulphur three drachms, Strychnia two grains; Alcoholic Extract of Black Cohosh one drachm, or a sufficient quantity; mix, and divide into sixty pills, of which one is a dose, and should be repeated three times daily, in conjunction with the above tincture. The throat and chest should also be bathed two or three times a day with the Compound Liniment of Oil of Amber.

Other remedies have, however, proved serviceable in the cure of the disease, as follows:

1. Take of Sulphate of Quinia, Extract of Stramonium, each, one scruple; Sulphate of Morphia two grains; Ipecacuanha six grains; Capsicum twenty grains; mix, and divide into twenty pills. One pill is a dose, to be repeated three or four times a day.

2. Take of Extract of Indian Hemp one drachm, Extract of Liquorice, Extract of Dandelion, each, one ounce, Salt of Tartar half an ounce, Water half a pint, Gin one pint and a half; mix, and dissolve. The dose is a tablespoonful, three or four times a day.

3. Take of Sunflower Seed two ounces, Cramp Bark, Rosin Root (*Silphium*), each, one ounce, Sheep Laurel Leaves half an ounce, Stramonium Seed two drachms, Gin or Whisky three pints; mix together and form a tincture, the dose of which is from thirty to sixty minims repeated three times a day. To be used in conjunction with the following: Take of Citrate of Quinia and Iron with Strychnia two drachms, Alcoholic Extract of Aletris, one drachm; mix, and divide into sixty pills, of which the dose is one pill, to be repeated three times a day.

4. Bromide of Ammonium will also be found a very useful agent to allay pulmonary nervous irritability. And in cases termed "humoral asthma," due to some peculiar condition of the blood, or, to the presence of a blood disease, this agent, together with the Bromide of Potassium, or the Iodide of Potassium or of Ammonium, will frequently be found very useful. Indeed, the Bromide of Potassium in doses of fifteen or twenty grains, repeated once or

twice a day, has, in many instances, proved very effectual in preventing a return of asthma.

In all cases of asthma, the most rigid attention to hygienic measures is required, as, regularity of the bowels, kidneys, and skin. Every day or two the whole surface of the body must be bathed with a weak alkaline solution, drying with considerable friction; every fine day the patient should exercise moderately in the open air; damp atmosphere, damp rooms, exposures to cold, and all known causes of an attack must be positively avoided; sleep should be limited to eight or nine hours daily, the bed being rather hard; and the sleeping apartment should be kept well ventilated. The diet should be nutritious, thoroughly masticated, of easy digestibility, and not liable to irritate, produce constipation or flatulence. Acids, pastry, hot bread, high-seasoned food, sweetmeats, and all intoxicating liquors should be positively prohibited. In most cases, asthmatic patients can take a reasonably full meal at the breakfast hour without incurring the risk of an attack; dinner and supper should never be hearty, but moderate, and in many instances, supper will have to be dispensed with altogether. Late suppers especially, must be avoided.

TUBERCULAR CONSUMPTION.

Tubercular Consumption or Phthisis Pulmonalis is one of the most distressing and fatal maladies to which the human family is subject; chiefly selecting the young of either sex as its victims. It is more common in certain northern latitudes, depending probably upon the frequent atmospheric changes occurring therein; and is occasionally met with in the warmer latitudes. It is not generally considered a contagious affection; though instances have occurred where, after sleeping for some time with a patient in the latter stages of the disease, persons supposed to be predisposed to it have shortly thereafter been attacked by it; this point is still one of discussion, and from the facts that have been observed by various physicians, it would appear to be safer for individuals, whether predisposed or not to phthisis, not to be too closely innated with patients in its latter stages. Females appear to be more liable to the disease than males; but whether this is owing to the excess in number of females over males in the civilized world, I am not prepared to state. It may prove fatal in three months, usually in six, and often continues for a much longer period.

The *symptoms* of consumption vary according to the stage of the

disease. Dr. Edward Smith in a work entitled—"Consumption ; its Early and Remedial Stages,"—describes a period of the disease,—a state of cachexia, or a dyscrasia, existing as a morbid condition antecedent to the tubercular deposit, which he terms the *first*, or, *pretubercular*, (*precursory*, Lawson), stage of the disease, and which constitutes the real disease,—the persistence and progress of which gives rise to the various pathological changes subsequently observed. This stage may always be noticed among those who are constitutionally predisposed to phthisis, but is usually less marked among those in whom it occurs accidentally ; it is the commencement of a positive morbid action, invariably resulting in a deposition of tubercles, unless it be promptly arrested ; in a few instances it may be absent, or if it does exist, it may be in such a minor degree as not to be readily apparent. This pulmonary stage does not invariably present the same features in every instance ; they will be found to vary, one set being present with some, another set with others, and so on,—and in those of a marked scrofulous diathesis, or of a strong tendency to phthisis, they will be much more emphatic. These symptoms will generally present several of the following characters, depending upon the temperament, the mental and nervous organization, and the natural degree of excitability of the patient:—There will be a defective condition of the vital powers, as manifested by an unusual vivacity of spirits in the earlier part of the day, alternating with a great depression of spirits during the latter part ; in those of lymphatic temperament, the lowness of spirits will be present almost constantly, rarely alternating with an opposite condition ; the digestive functions are always more or less deranged ; the appetite being irregular, capricious, and uncertain, more or less distaste for fats, meats, acids, or sugar, and often, milk, tea, or coffee,—the tongue being more or less coated with a white film, sometimes brownish or yellowish, its body pale, large, and flabby, except in cases where some irritation is present, when its body will be more or less red, and not unfrequently the papillæ will be observed quite prominent,—in those of sanguine and nervous temperament, the tongue will frequently remain clear, and retain its usual size, color, and appearance,—the amount of food taken will generally be less than previously consumed, although the patient may not be aware of it, until his attention is directed to it,—and after meals there will be a sense of oppression, tenderness upon pressure over the epigastric region frequently observed at any period of the day,—more or less acidity of the stomach, an acid taste in the mouth, and flatulency. Assimilation of food is defective, as shown by the want of nourishment of the general sys-

tem, the weight of the body, as well as its bulk, becoming more or less considerably lessened, but being influenced in some degree by atmospherical conditions, as well as by the kind of food and quantity of fluid taken, and by the degree and amount of exercise. The skin is usually thin, fair, and very sensitive, soft, and cool, and disposed to perspire upon the slightest causes, the perspiration frequently being very acid, so as to be detected by the odor, and perspirations during sleep are generally observed; sometimes, the perspiration is quite offensive, and again, in some cases, it may be abundant without giving off any sour or offensive odor, in which case, considerable debility is apt to be present; indeed, as a general rule, consumptives are predisposed to an abnormally acid condition of the perspiration, which is apt in a few days to stain the linen of a yellowish color; coldness of the extremities is a common symptom; there is a diminished temperature of the body; a diminution of muscular strength, with a corresponding loss of tone and softness of the muscles,—exercise readily produces fatigue,—running up stairs causes shortness of breath and palpitation,—bodily vigor gradually diminishes,—the pupil enlarges, giving a bright and somewhat staring appearance to the eyes,—and the expression of the countenance becomes altered, the face and skin being sallow or pale, the pallor being unlike that of anemia, with a look of languor and want of vivacity. The circulation is feeble and somewhat quickened, the pulse being variable, but generally slow, feeble and excitable. Respiration is shorter, shallower, feebler, and perhaps quicker. There is an apparent diminution of power to respire, with a loss of bulk of the pectoral muscles, the intercostals, and the muscles of the back. Innervation is invariably lessened more or less considerably.

With these general symptoms, there will frequently be associated others of a secondary, but no less important character. Thus, among females there is a strong disposition to leucorrhœa, and to amenorrhœa, as well as to other menstrual disturbances. Muscular pains about the chest are very common, especially in the pectoral muscles, and in the muscles attached to the base and inferior angle of the scapula; the former being changeable, increased on deep inspiration, and more common to males; the latter being more common to females, and increased on deep inspiration, or upon moving the arms. The throat is often excessively sensitive, sometimes presenting a paleness of the whole mucous membrane, an apparent elongation of the uvula, a frothy state of the whole throat, a sense of constriction in breathing, and sometimes in swallowing, and a great sensitiveness to the presence of foreign bodies, as the tongue-

spatula, etc. In other instances, pharyngo-laryngeal disease will be present. Sometimes, cough is present, being a reflex act resulting from irritation applied directly to the true seat of the act, the pharynx, or transmitted from distant organs, as, in the bronchi, stomach, pulmonary structure, etc. The cough is short, not severe, and is excited when exposed to a cool, or to a cool and moist atmosphere; sometimes it is increased after meals, or from irritating condiments, and frequently occurs immediately after coition. A small amount of expectoration is often present, occurring more especially in the morning, and is ordinarily due to pharyngeal, or pharyngo-laryngeal disease. The expectoration is glairy, semi-transparent or slightly opaque, more or less tenacious, not frothy, unless associated with bronchitis or pharyngeal irritation, and contains tessellated epithelial cells from the lower part of the pharynx, with large black cells, filled with nuclei and granules. None of the yellow elastic structure of the lungs is found at this stage; but ciliated epithelium, which lines nearly the whole nares and covers the nasal aspect of the soft palate and the nasal end of the pharynx, is also frequently present, especially in those cases where the nasal secretion is very abundant, and much of it passes into the pharynx. As the bronchi, trachea, and larynx, also have ciliated epithelium, its presence in this sputa has sometimes been erroneously attributed to these organs. Occasionally, the expectoration will contain small pellets of a white, soft character, which, when dried, resemble chalk. They are of various sizes, are rarely expectorated in cases in which the disease proceeds to a fatal termination, (except when they occur in the advanced stages), and it is doubtful whether they originate in the lungs. Spitting of blood may also be present in this precursory stage, but not always. It is usually very small in quantity, and is generally derived from the mucous surface of the pharynx and fauces, very seldom, if at all, from the lungs, at this early period; though it may occur from rupture of a small vessel upon the mucous lining of the larger air-tubes, and is probably due to a state of local congestion or increased vascularity, but not necessarily connected with the condition of the lungs. In a few cases, vomiting occurs, more frequently after a meal, always associated with a cough, and is not due to dyspepsia.

In connection with the preceding symptoms, are those of the lungs and chest. Upon an inspection of the chest of a person in the first stage of phthisis, a flattening below the clavicles, and a falling in above the clavicles at the site of the apices of the lungs, will be observed, usually on one side—the diseased side,—the pectoral muscles of each side will also vary in size, and the intercostal

muscles will not exhibit their normal fullness, there will be a tendency to roundness of the shoulders, also to an increase of width between the scapulæ, and flatness above the transverse processes of the scapulæ. At the lower part of the thorax there will be no unusual expansion. The respiratory movements of the chest, especially at its upper anterior and lateral parts will be found lessened; while at the back these movements will be so indistinct as to be detected with difficulty,—of course these diminutions of respiratory movements will be observed more markedly on the sides subsequently affected with tubercles, and will vary in amount with each person, according to the amount of deviation from health,—they are invariably present, and gradually increase, leading to other abnormal conditions. Women usually have much more breath movement at the upper part of the chest than men, hence there may be much diminution of it in diseased females, and yet they will present an amount remaining, equal to that which occurs in men,—this is important to note. There will be no increase in the abdominal movements. The force and fullness of the respiratory efforts will be lessened, while the inspiratory effort will be short and feeble, and incapable of fully expanding the chest. These symptoms gradually induce a condition of lessened vitality of the air-vesicles of the lungs, and an unusual tendency to the reception of morbid matters, resulting in tubercular deposits.

In this early stage of the disease, before there is any evidence of the deposition of tubercle, and after it has existed for some time with diminished expansion of the lung, percussion will elicit an appreciable degree of dullness on the clavicles, and, perhaps, over the chest in general, arising, no doubt, from the absence of a full amount of air in the lung tissue. It is generally observed upon one side only, occasionally on both. Auscultation will detect the respiratory murmur feeble, lessened both in force and fullness, and of diminished length,—particularly at one or both apices. If a forced inspiration be made with ease, regularity, and moderate force, the vesicular or respiratory sounds become more normal. A rapid, jerking, or forcible inspiration will develop other sounds, and must be avoided. No rales or signs of bronchitis are present; but if there should be, it will be difficult, if not impossible, to detect the lung disease until they have disappeared.

No particular *pathological appearances* are observed in the lungs in this stage, unless it be toward its termination, when the first elements of tubercular deposition may be seen, consisting of the tubercle cells, which are ordinarily first observed, in greater or less abundance in the least movable parts of the lungs, that is, in their apices,

and which greatly resemble the nucleus of the epithelium cells, with which tubercular deposits may in some way be associated.

It will be observed, that many of the above-named symptoms may be met with in other pathological states of the system than those tending to result in tuberculosis of the lungs, and that a medical man would not be justified in diagnosing the presence of a tuberculous dyscrasia upon them alone. Again, the presence of others of the symptoms referred to, would indicate the actual existence of tuberculous deposit at an early period. Yet, as Dr. Smith has had considerable experience in the treatment of phthisis in the Brompton Hospital, and has undoubtedly bestowed much attention upon this early stage of the disease, we must not too hastily reject his views, but should carefully consider them, with a hope that if not wholly correct, they may lead to other and more perfect information concerning a period of the disease at which we would naturally suppose it to be more amenable to a proper management than at any other. I have, therefore, given the above condensed statement of the results of his investigations, deeming them of sufficient value to interest every physician.

The *first stage*, or early period of tubercular deposits in the lungs, (as usually recognized by physicians,) may present such trivial symptoms as to escape the notice both of the medical man and the patient; or, there may exist a feeble condition of the system, a gradual decline of nervous and muscular energy, a lack of assimilation, without any symptoms by which the disease may be located, or even its nature determined. And this condition may continue for a considerable length of time, until from exposure to an exciting cause, symptoms become rapidly developed, indicating the latter period of the first stage of phthisis, or, the early period of the second stage. Thus we frequently observe that the first symptoms of phthisis are manifested only after an exposure to cold, an attack of pleuritis, or pneumonitis, or, some imprudence in diet.

We must, however, except, from the apparently passive condition just referred to, those instances in which one or both of the progenitors of the patient were affected with phthisis, or where, from lack of pulmonary nervous and muscular power, the peculiar consumptive form of the chest has become developed,—in which instances, it is hardly possible to mistake the true condition of the patient, even at a very early period.

The symptoms ordinarily present, during the first stage of consumption, are, a sense of languor; debility; slight dyspnoea, or shortness of breath, which is much hurried upon physical exertion; and the patient loses in weight. Cough is a very early symptom, it may

be slight, dry, and hacking at first, perhaps induced by a tickling sensation in the trachea, and gradually becomes more frequent and distressing, and attended with expectoration. The expectoration is thin, frothy, transparent; resembling mucus, and, sometimes is dotted or streaked with blood. Indeed, more or less hemoptysis will, in some instances, be the first apparent symptom of phthisis manifested. Pains, at first slight and transient, will be experienced; sometimes, they may be constant; at others, intermittent. Pain is frequently located at the shoulder-joint, and is accompanied with tenderness of the sub-clavicular region; in other cases, it is felt, at first, under the sternum. There is usually a degree of sensitiveness to cold, coldness of the extremities, and a livid or dark appearance of the lips, and roots of the finger nails. With females, amenorrhea is very apt to occur.

At an advanced period of the first stage, these symptoms increase, the breathing becomes more difficult; the cough more severe and distressing; the face flushes, particularly after eating; the palms of the hands and the soles of the feet, are affected with burning heat; the appetite is variable and capricious; the bowels are irregular; the urine is high-colored, depositing a red sediment; the pulse may be natural, or, soft, small, and a little quicker than usual,—sometimes full, hard, and frequent; the tongue may be clean, or present a thin white coat along its center, or toward its root, especially if digestion is impaired; the tip of the tongue, as well as its edges are red; and, even in this stage, hectic fever and night sweats may be present. A very common appearance in the early period of the disease, is a delicate, pearly, transparent appearance of the margin of the gums; occasionally this streak will be reddish. The conjunctiva is pearly white, or slightly bluish.—The fever attending this stage, is remittent, and has in many cases two exacerbations a day,—the first occurring about noon, and the other during the night, or toward morning, generally terminating in a sweat. The symptoms named, will vary considerably with different persons, according to the progress of the disease, the degree of tuberculous dyscrasia, and other modifying circumstances that may be present.

In this stage, there is present a greater or less amount of crude tubercles, which may be disseminated over the entire lung, but are more commonly accumulated near the apex of one or both of the lungs. Bayle observes that the lower lobes of the lungs are affected in chronic bronchitis; but that the upper are affected when tubercles are deposited. As soon as the elasticity of the lung tissue is interfered with by these deposits, percussion will detect a deficiency of the clear or pulmonary resonance in the upper part of the

chest,—over, above, and below the clavicle, and over the scapula,—as compared with that of the opposite side, together with more or less dullness, according to the approach toward an increased density of the lung from consolidation, and a corresponding increase of resistance. Auscultation will detect a shortened inspiration, and a marked prolongation of the expiratory murmur, owing to an impaired condition of the elasticity of the lungs; the vesicular resonance also loses its soft, vesicular character, and becomes rough, and harsh; occasionally, dry crackling, and crumpling sounds will be present; the crumpling sound being usually heard only during inspiration. Bronchophony will also be heard at the apex. If bronchitis be present, its physical signs may also be noticed in addition. (*See Note*, page 539, *sections 1 and 2*.)

The *second stage*, or period of consolidation, in which the tubercles increase both in number and size, so as to compress and obstruct the substance of the lung, presents symptoms similar to those already named as characterizing the advanced period of the first stage, but are of much greater severity. It must be recollected that there is no distinct line of demarcation between the several stages of consumption, but that they gradually pass one into the other. In this stage there will be an accelerated pulse; hectic fever; more difficult breathing; night sweats; a peculiar whiteness and lustre of the eye; a sense of constriction across the chest; cough more severe; great sensitiveness to cold; deep inspiration will produce cough, or occasion pains in the chest; cough or pain is increased when lying upon the affected side; hemoptysis is often present; constipation; derangement of the digestive organs; increased loss of flesh; a red streak along the margin of the gums; a clubbed condition of the fingers; deep-colored skin around the root of the nails; the nails are frequently curved, and present a bluish appearance; and as the stage advances toward its latter period, chilly sensations, or actual chills will be experienced; which may come on at regular or irregular periods; and sometimes diarrhea, or an irregular condition of the bowels will be present. As in the first stage, some of these symptoms may be absent, or the symptoms may vary with different individuals.

But this stage is more positively determined by the physical signs. Inspection will detect an unequal expansion of the chest, especially at its upper part. Percussion will elicit a more marked dullness in the upper part of the chest than in the first stage; there will also be a greater degree of resistance to the percussing finger; and a smart blow upon the intercostal muscles will often produce an irritable or quivering action of these muscles. Aus-

cultation will detect a diminution in the duration and intensity of the inspiratory murmur, while those of the expiratory murmur will be increased, at the upper part of the chest. In health, the expiratory murmur is about one-third as long as that of the inspiratory; while, in phthisis, the former becomes frequently equal to, and even considerably more prolonged in duration than that of the latter; while the latter becomes much diminished. Very frequently the inspiratory murmur will be interrupted in the sub-clavicular region, the air seeming to enter the lungs at this point by a succession of waves, instead of in a continuous stream, giving rise to the wavy, or jerking inspiration; taken alone, this sign is no evidence of phthisis, but it is of value when associated with prolonged expiratory murmur, and other changes. Dry crepitation, or dry crackling sounds will be more distinctly observed at the apex of the lungs; the vesicular murmur will be feeble or even absent; bronchial respiration and bronchophony will be more marked; while the lower lobes of the lungs will yield puerile respiration. The heart's sounds may frequently be heard in the sub-clavicular region of one or both sides. Vocal fremitus may also be observed, especially under the shoulder-blades.

Frequently the signs of bronchitis are present, and mask the respiratory murmurs; or, friction sounds from local pleuritic lesions, etc., may exist. If a doubtful sound is removed by cough, in either stage of the disease, or, is superseded by vibration sounds on deep inspiration, it is neither dry crepitation or crackling, nor moist crepitation. A bellows murmur is indicative of anemia. (*See Note, page 539, sections 1, 2, and 16.*)

There is a peculiarity that has been observed relative to the pulse of a consumptive; thus, we have strong grounds for suspecting the existence of phthisis when a patient's pulse is above ninety beats in a minute, and he is, at the same time, not much disqualified for exertion. Again, in a state of health, when a person is seated in an easy chair, with his back supported, if his pulse be examined, it will be found to beat slower than when he subsequently assumes the standing position, by from twelve to eighteen beats; in phthisis, the pulse is much less easily accelerated by changes of posture, being equal in either of the above-named positions, or, at all events, with a difference of only four or five beats. The pulse of a consumptive will also be found to vary considerably on different days; and on those days when the pulse is least frequent, the difference produced by change of posture will be found the greatest.

The *third stage*, or period of softening and formation of cavities

may be ushered in with chills occurring at regular or irregular periods, but these are not always present. It is chiefly characterized by increased shortness and hurriedness of respiration; an almost constant cough, often deep and hollow; the voice changed, often being weak and hoarse; the expectoration purulent, greenish or yellowish, flocculent, nummular, sometimes of a dirty-grayish appearance, and showing under the microscope pus-corpuscles, exudation globules, pieces of the structure of the lungs, and granular bodies which are considered as indicating the existence of tubercles—cheesy particles may frequently be noticed in the sputa, especially in an early period of this stage—and, in some instances, the expectoration will contain more or less blood. Debility and emaciation become greatly augmented; the features become sharp; the eyes hollow and languid, or clear and bright with dilated pupils; the nails curve inward and are more or less livid in color; the cheek bones become prominent; the hair falls off; hectic fever occurs every day; the feet and ankles become œdematous; night or morning sweats are very profuse and debilitating; the urine will be found to contain an excess of uric acid, also euroerythrin, and, if indigestion be present, oxalate of lime crystals—the sediment of urates is usually of a reddish tint—sometimes the urine is pale and turbid, termed “anemic,” and which is apt to occur after considerable hemoptysis, and it soon takes on an ammoniacal, offensive odor in many cases—occasionally, sugar is detected in the urine. Colliquative diarrhea continues obstinate and unyielding; a few weeks previous to dissolution aphthous ulcerations are apt to attack the mouth; and occasionally the patient becomes delirious. More commonly, however, the senses remain to the last, not much impaired, and a peculiar feature of this disease is, that those suffering from it are seldom apprehensive of danger, but flatter themselves with a speedy recovery, the mind being confident and full of hope. The difficulty of breathing is often very distressing in this last stage, and, not unfrequently bed sores (*paratrimma ad decubitus*) are produced, which add greatly to the sufferings of the patient. Death may occur from debility; from peritonitis following intestinal ulceration; from sudden pulmonary congestion; from hemoptysis; from an accumulation of air in the pleural cavity; from exhaustion, etc.

In this stage, at first, the physical signs do not differ much from those already described in the second stage, the dullness on percussion, prolonged expiratory murmur, dry crackling rales, bronchial respiration, bronchophony, etc., being nearly equally marked in the latter period of the second, and the early period of the third stage.

But as the tubercle and lung tissue commence to soften and break down into fluid matter of greater or less consistence, giving rise to cavities in the lungs, other signs will be observed. At first, there will be a still greater inequality in the expansion of the two sides; percussion will elicit a dull sound if the walls of the cavity be dense,—but if they be thin, a tympanitic, amphoric, tubular, or bruit de pot fêlé resonance may be obtained, (*see* page 523); auscultation will detect clickings or moist crepitation in the subclavicular region, indicative of softening,—when cavities form, cavernous respiration will be heard, gurgling, or splashing rales, pectoriloquy, amphoric resonance, cavernous gurgling attending cough, metallic tinkling,—if the cavity be small, a cavernulous rale will be heard,—also, cavernous metallic cough may be observed in the interscapular region. The sounds of the heart may also be very clearly and distinctly heard at the upper part of the chest over the cavity, and a waving impulse in the second intercostal space may frequently be appreciated. (*See Note*, page 539, *sections* 19, 20, 21, 22, 23, and 26.) It must be recollected, however, that should emphysema, or other lesions be present, in addition to those of the tuberculous affection, their physical signs will be superadded, perhaps masking or modifying some of those just named.

Pulmonary phthisis must be *diagnosed* in its various stages, from chronic bronchitis, chronic pleurisy, chronic pneumonia, cancer of the lung, bronchial dilatation, abscess and gangrene of the lung, and which may be effected by carefully observing the physical signs which have been named under each of these diseases, as well as in the quotation from Dobell, in *Note* on page 539.*

* The following remarks relative to the diagnosis of tuberculous phthisis, by Dr. Walshe, will be found of much practical utility to the physician: "A young adult who has an obstinate cough, which commenced without coryza, and without any obvious cause, a cough at first dry, and subsequently attended for a time with watery or mucilaginous-looking expectoration, and who has wandering pains about the chest, and loses flesh, even slightly, is, in all probability, phthisical. If there be hemoptysis, to the amount of a drachm even, the diagnosis becomes, if the patient be a male, and positively free from aneurism or mitral disease, almost positive. If, in addition, there be slight dullness under percussion at one apex, with jerking, or divided and harsh respiration, while the resonance of the sternal notch is natural, the diagnosis of the first stage of phthisis becomes next to absolutely certain. But not absolutely certain; for I have known every one of the above conditions exist, (except hemoptysis, the deficiency of which was purely accidental), when one apex was infiltrated with encephaloid cancer, and no cancer had been discovered elsewhere to suggest to the physician its presence in the lung. If there be cough, such as described, and permanent weakness and hoarseness of the voice, the chances are very strong, (provided he be non-syphi-

Phthisis in its first stage may readily be confounded with *chronic bronchitis*, as, cough and expectoration accompany each malady. No positive diagnosis can be made when the bronchial physical signs are present, until percussion elicits dullness, especially at the

littic), that the patient is phthisical. If decidedly harsh respiration exists at the left apex, or at the right apex behind; if the rhythm of the act be what I have called cog-wheel, (wavy or jerking), and there be dullness, so slight, even, as to require the dynamic test for its discovery, there can be little doubt of the existence of phthisis. If, with the same combination of circumstances, deep inspiration evokes a few clicks of dry crackling rhonchus, the diagnosis of phthisis, so far as I have observed, is absolutely certain. If these clicks, on subsequent examination, grow more liquid, the transition from the first to the second stage may be positively announced.

"If there be slight flattening under one clavicle, with deficiency of expansive movement, harsh respiration, and slight dullness under percussion, without the local or general symptoms of phthisis, the first stage of tuberculization can not be diagnosed with any surety, unless there be incipient signs at the left apex also; the conditions in question, limited to one side, might depend on chronic pneumonia, or on thick induration matter in the pleura. The existence of limited though marked dullness under one clavicle, with bronchial respiration and pectoriloquy, so powerful as to be painful to the ear, the other apex giving natural results, will not justify the diagnosis of phthisis. I have known this combination when the apex of the lung was of model health, and a fibrous mass, the size of a walnut, lay between the two laminae of the pleura. I would even go further, and say, that the combination in question is rather hostile than otherwise to the admission of phthisis, as, had tuberculous excavation formed at one side, the other lung would, in finite probability, have been affected in an earlier stage.

"Pneumonia limited to the supra-and infra-clavicular regions on one side, and not extending backward, is commonly, but not always, tubercular. Subcrepitant rhonchus, limited to one base posteriorly, is not, as has been said, peculiar to tubercle; it may exist in emphysema, and in mitral disease. Chronic peritonitis, in a young person aged more than fifteen years, provided cancer can be excluded, involves as a necessity tubercles in the lungs; to this law of Louis, it is necessary to add the qualification—provided Bright's disease be also absent. Pleurisy with effusion, which runs a chronic course in spite of ordinary treatment, is, in the majority of cases, tuberculous, or cancerous; the character of the symptoms previous to the pleurisy, will generally decide between the two. Double pleurisy, with effusion, is not, as has been said, significant of tubercle; for it may depend on Bright's disease. If the latter disease can be excluded, carcinoma and pyohemia remain as other possible causes. If a young adult free from secondary syphilis, and spermatorrhea, and not dissolute in his habits, speedily lose flesh without clear cause, he is, in all probability, phthisical, even though no subjective chest symptoms exist. But he is not by any means certainly so, for he may have latent cancer in some important organ, or he may have chronic pneumonia. Nay, he may steadily lose weight, have dry cough, occasional diarrhea, and night sweats and present dullness under percussion, and bronchial respiration under both clavicles, and yet be non-phthisical. I have known all this occur in cases, both when the lungs were infiltrated superiorly with primary encephaloid cancer, and

apex of the left lung. Wasting, and loss of weight are usually much greater in phthisis than in bronchitis, and in inherited cases, the peculiar consumptive formation and appearance may be present.—In *chronic pneumonia* many of the symptoms resemble those of phthisis, as, cough, wasting, vocal fremitus, sinking in of the thorax, prolonged expiration, feeble inspiration, etc. But, in pneumonia, there is its previous existence, besides, there is less emaciation than in phthisis, and the physical signs of consolidation are almost always confined to one lung only, and over its lower lobe; in phthisis, it is the apex where the dullness, etc., are observed. Yet it must be observed that phthisis may appear, at first, in the lower lobe, and pneumonic consolidation take place at the apex of the lung, in which rare instances, the diagnosis will be extremely difficult. Hemoptysis does not occur in chronic pneumonia, except, perhaps, a slight streaking of the expectoration with blood. In obscure cases, the physical examinations should be frequently repeated, to ascertain if deposit continues to occur, affecting those parts of the lung that were healthy at previous examinations; an extension of dullness, with the signs peculiar to the second and third stages will clear up all doubts.—In *chronic pleurisy*, the dullness at the lower part of the lung, the great feebleness or entire suppression of respiratory murmur, the lessened or absent vocal fremitus, together with less constant and severe cough, less emaciation, but little, if any, night perspirations, and no hemoptysis, will determine pleurisy from phthisis. If there be a flattening or falling in of the thorax in chronic pleurisy, it almost always occurs on one side only. Chronic pleurisy, the same as chronic pneumonia, may be associated with phthisis, the physical signs of tubercular deposit at the apex of the left lung, or of both, will be conclusive as to the consumptive disposition.

Cancer of the lung is a rare disease, and most commonly affects but one lung; the side affected is flattened, the dullness on percussion is much greater than in phthisis, respiration may be feeble or absent, or loud and sonorous, with an entire absence of rales,—the pain is more acute and constant than in tubercle, the skin presents the peculiar cancerous aspect, and the expectoration is purulent, frequently resembling currant-jelly. However, tubercle and

when they contained secondary nodules of the same kind. Failure of weight becomes less valuable as a sign of phthisis, the longer the thirtieth year has been passed. The discovery of cardiac disease with marked symptoms, deposes against, but does not exclude, the existence of active tuberculization. The existence of cancer in any organ is unfavorable to the presence of tuberculous disease, but tubercles and cancer may co-exist in the same lungs."

cancer seldom exist together.—*Bronchial dilatation* may be determined from phthisis, by the disturbance of the general system being much less than that of the latter disease, by the cavity formed by the dilatation being at the central or lower part of the lung, instead of at the apex, with very slight dullness on percussion, and by its being of a stationary character, or changing very slowly; there will also be a more profuse expectoration, sometimes offensive. Night sweats and hemoptysis are absent, and the affection usually occurs at a later period in life than phthisis. In sacculated dilatation there will be a large and coarse dry crackling.—*Abscess of the lung* may also present many of the symptoms of phthisis, but the profuse, fetid, and purulent character of the expectoration, the physical signs of a cavity being at the lower lobe of the lung, but one lung being diseased, and the general system being but slightly impaired, will determine it from the tuberculous affection.—*Gangrene of the lung* also affords the signs peculiar to a cavity, as well as the constitutional disturbances of phthisis, but may be discriminated from the latter malady by the dirty grayish or greenish or dark-brown color and sanious aspect of the sputa, its accompanying fetor, and its subsequent purulent character and diminution or cessation of the fetor. In conjunction with this, the breath is persistently and almost insupportably fetid, being worse during or immediately after coughing. It is more common among children, and is rare in advanced age.

In the diagnosis of phthisis we must recollect that the disease depends upon a peculiar dyscrasia, and is preceded and attended with many of the constitutional disturbances already named; that, as a general rule, the deposition of tubercles commences in the apex of the lungs, usually the left one first, but soon involving the right. Its physical signs are similar to those of other pulmonary lesions, but in no disease do they occur in the same order and combination. Sometimes, even after large cavities have formed, the tubercles become transformed into a cretaceous substance, and instead of tuberculous matter in the expectoration, calcareous masses of larger or smaller size are met with, and this change may be followed by an augmentation of the symptoms and death,—or, the symptoms, as well as the health and strength of the patient, may gradually improve, until all the consumptive indications disappear.

The *cause* of tubercular phthisis is not well understood; it appears to be a peculiar condition of the blood, or of the blood and nervous system, manifested by a feeble vitality, which is ultimately followed by the deposition of tuberculous matter, usually on sur-

faces of membranes possessing an epithelial covering; this tubercular element simply accumulates by new deposits, is unorganized, has its own tendency to decay, and, acting as a foreign body, it interferes with the supply of blood to the parts as well as with the vital functions of the organs containing it, disposing them to decay and disorganization. Thus the tubercle is not the disease itself, but simply one of the results of the disease. Why the lungs are selected for the deposit of the tubercle is, probably, from a want of proper vital integrity in these organs. The disease is almost invariably met with among persons of feeble vitality, either from hereditary transmission, or from accidental causes. The results of post-mortem examinations tend to prove that tubercles may exist in the lungs for years, even to old age, without occasioning any indications of their presence, unless aroused into action by some of the exciting causes.

A predisposition to phthisis is frequently transmitted by parents of feeble vitality to their children; and these, by a proper course of living, may so far check the disease, as to render it latent for several generations, when, under the influence of impaired vitality and the exciting causes, it will re-appear. My own view of the subject is, that, by a proper course of hygienical and therapeutical management, commencing in early childhood and persevering in the measures until adult age, and continuing it for a few generations, a proper amount of vitality may be imparted to the constitutions of, otherwise, tuberculous individuals, and the disease be wholly and thoroughly eradicated from them. Those who appear to be more liable to tubercular phthisis are, generally, of slender make, with long necks, prominent shoulders, narrow chests, fine, clear skin, fair hair, and delicate, rosy complexion; sometimes there will be a disproportionate thickness of the upper lip, a weak voice, perhaps large veins, and great sensitiveness,—but much variation will be observed in these respects. Among 1010 phthisical patients admitted into the Brompton Hospital, nearly one in every four was the offspring of a consumptive parent.

Among the exciting causes which give rise to the disease, or cause its development when existing in a latent condition, none stand more prominent than colds; indeed most patients date the beginning of their pulmonary malady from lying in damp beds, wearing wet clothes, wetting their feet, exposure to a cold damp air, passing, in a state of perspiration, quickly from a warm apartment to cold air, as from a ball-room or other crowded place, and to other circumstances of a similar character. Females appear to be more liable to the disease than males, owing to the peculiar circum-

stances by which they are surrounded; in the young, the disease is more common from the twentieth to the thirtieth year, and in the aged, from the fiftieth to the eightieth.—Among the other exciting causes, may be named the following: damp air; want of exercise; sedentary habits; unwholesome and insufficient food; too early mental application; depressing mental influences; excessive cares; masturbation; sexual excesses; premature or unsound marriages; prolonged lactation; improper treatment of certain maladies; tight lacing; dwelling in damp and confined places; inhalation of deleterious gases; suppression of accustomed evacuations; inhalation of particles of dust, as, among millers, stone-cutters, etc.

The *prognosis* of phthisis depends upon circumstances; that it is a curable disease does not admit of a doubt—but its curability is governed by certain conditions, as, the strength of the predisposition, the state of the general system, the extent and advance of the tuberculous formations, and the stage in which the treatment is commenced. The earlier the period at which the patient can be placed under treatment, the greater will be the chances of cure; in the second and third stages, although cures have been recorded, still the prognosis must always be regarded as unfavorable. Perhaps it would be more truthful to state that, although cures have been observed after the deposit of tubercle, they are but few, and also, that in no case can the practitioner honestly predict a favorable issue.—Hereditary consumption is less controllable than acquired consumption; when the acquired disease occurs in a strongly-marked strumous diathesis, it is also more intractable to treatment. When the tuberculous dyscrasia exists in a minor degree, tubercles occupying only a limited portion of the lungs, a cure may be effected, even after softening has occurred, provided no large cavity be formed; the greater the tuberculous dyscrasia, and the more extensive the deposit, the more unfavorable will be the prognosis.

A persistent anorexia without any attributable cause, deficient powers of digestion, and, on eating considerably, a sense of gastric oppression and weariness of the extremities, are symptoms very favorable to the development or extension of phthisis, in any stage. “When hectic fever has become fully established, the patient is seldom free from diarrhea, perspirations, or profuse expectoration, which seem to exhibit toward each other a certain degree of antagonism. In proportion to the increase of one, the others have a tendency to diminish; and as one becomes checked by treatment, another too often makes its appearance. The issue of nearly every

fatal case of phthisis is immediately attributable to the exhausting effect of one or other of these three symptoms; hence it becomes a matter of practical value to ascertain their comparative influence upon the patient. Diarrhea is the most rapidly destructive; perspiration the next; and expectoration the least so." (*R. P. Cotton.*)

An increase in the weight of the patient, associated with a more healthy condition of the urine is always favorable; yet it must not be forgotten, that frequently the patient will attain a flattering degree of improvement, and then fall back, the power of reparation not being equal to the destructive agency.—Pregnancy may, for the time, arrest the progress of the phthisis, but will not cure it.

Severe cough, profuse expectoration, quick pulse, hectic fever, and night sweats may be present, without any tuberculous affection of the lungs; these symptoms arising from other causes, and yielding to appropriate treatment.

The *pathological appearances* vary according to the stage of the disease. In the first stage more or less numerous tubercles will be observed in the lungs, of various sizes, from that of a small speck to that of a hazel-nut; the smaller ones may be gray and translucent, or colorless and transparent, but as they increase in size they become yellowish and opaque, the yellow speck being first observed in the center. The bronchial and pulmonary tissues in the neighborhood of these deposits may exhibit redness and vascularity, or there may be no perceptible change. Under the microscope, the tubercles appear to be air-cells filled with tuberculous deposit, consisting of granules, tubercle-corpuscles, and non-cellular elements, and sometimes, pus, granular cells, mineral matter, and cholesterine.

In the second stage, these tubercles have lost their firmness, become broken down, and softened; and their softened, pultaceous matter, passes into the bronchial tubes, from whence, during life, it is expectorated. In this stage, pleuritic adhesions may also be observed, from adhesive inflammation.—In the third stage, the substance of the lungs may be so filled with tuberculous matter as to leave but few traces of its original structure; the softening of the tuberculous masses gives rise to cavities, and ulceration, which destroy the lung tissue; these cavities may vary in size from that of a bean to that of an orange, their form depending entirely upon the directions followed by the softening and ulcerated processes, and they usually contain more or less fluid varying in consistence and color, though occasionally they will be empty and lined

throughout with a dense membrane. Sometimes an entire lobe may be converted into one large, jagged, irregular cavity, with bands of pulmonary tissue traversing it in various directions. Many other results of ulceration and disorganization will be observed. In a majority of instances, tubercles may be observed in various other organs of the body.—Should a cure have taken place, either cicatrices will be observed in the lungs, from the tuberculous matter having been expectorated, or absorbed, together with a loss of more or less air-cells to the lung, or, the tubercle will be observed dry, calcareous, and opaque, with dry and detached walls, and often surrounded by shrunken and obliterated lung tissue.

The *treatment* of tubercular phthisis consists of both hygienical and therapeutical measures, each of which is of much importance. Perhaps, of the two, the former is really the more useful and important, yet on no account should the latter be dispensed with; being careful, however, while pursuing it, not to drench the patient's stomach with such an abundance of nauseous mixtures and medicines as to interfere with its normal functions, or create a disgust toward all remedial agents. In the management of a consumptive patient the greatest care and circumspection is required, and the physician should undertake the treatment of no case unless both the patient and his or her friends will agree to strictly follow out the directions in every respect; and the directions must, in all cases, be made to conform as closely as possible to the circumstances and condition of the patient.

As being the first in importance, the hygienical measures will be considered the first. At the commencement, the patient must be removed from all conditions unfavorable to a restoration to health, as, from a foul, heated, or damp atmosphere, from exposures to cold, from sedentary occupations, from the use of tobacco in any form, from abuse of alcoholic drinks, and, masturbation or sexual contact must positively be forbidden. All sources of anxiety, mental despondency, or mental excitement must be removed as much as possible,—but moderate mental excitement, of a cheerful pleasing character, is allowable. The question is, not what we can do to satisfy the patient, or what indulgences we can permit but, what *must be done* in order to effect a cure,—and if the patient can not or will not adopt the necessary measures, there is an end of the matter as far as cure is concerned, and then all that can be done will be to smooth his passage to the grave. Having effected the changes just referred to, the next thing to consider is the diet. All food should be prepared so as to please the taste of the patient. The old-

fashioned plan, even still pursued by a few, of endeavoring to cure phthisis by depressing measures and a low diet, has been productive of much harm, because the lack of nutrition is as destructive to vital action as the disease itself. In this disease the blood must be enriched, and the body be sustained and nourished by proper nutritious diet, which will materially aid in the removal from the system of those elements which favor tuberculous deposits, as well as in effecting a change in the condition of the blood unfavorable to their existence. And, when the vital powers have been once aroused, the food requires to be much increased, to an extent not to distress or overload the stomach.

Nitrogenous food is required for the true transformation of the hydrocarbons, and for the supply of material to be fixed in the nitrogenous tissues. As drinks, water, milk, milk and water, cocoa, chocolate, tea, or coffee, may be used. The milk used should be new and good, taken from a healthy and well fed cow, and should be taken warm. If fats are tolerated, half an ounce of suet, cut finely, may be boiled in one pint of milk. If tea or coffee be used, about one-half of it should consist of milk; and, in cases of gastric acidity, lime-water one part may be added to milk two parts. The milk should be used freely. Beef tea, with salt, or with milk added, also affords considerable nourishment. In some instances, especially where there is a depressed action of the heart, stimulants will prove advantageous, when used in moderation, not sufficient to excite the brain, as, ale, porter, wine, and in many cases, even good French brandy. But these stimulants will not be required where there is an evident improvement going on.—The solid food must also be nutritious, easy of digestion, and not disposed to occasion acidity, flatulence, costiveness, or diarrhea. Of all meats, beef is the best, and pork the worst. The beef should be tender, either as a steak or a roast and should be “underdone” or “rare.” Tender mutton, poultry, game, rare-boiled eggs, oysters, salad oil, cod liver oil, neats’ foot oil, cocoa-nut oil, good sweet butter, cheese, etc., may also be freely used, together with baked potatoes, wheat bread, gluten bread, boiled rice, plain rice pudding, ripe fruits, lettuce, ice-cream, custards, etc.

The oils, referred to, especially the cod liver, have frequently proved so useful in this disease, as to be considered therapeutic agents,—but they are nutrients, articles of diet also. When they can be obtained pure, they will prove beneficial; but when manufactured from or mixed with lard or some other oils, they are of little value. They may be given in teaspoonful doses, gradually increasing to a tablespoonful, two or three times a day, or as often

as the stomach of the patient will permit. They may be rendered palatable by having them taken in Brandy, Gin, or Whisky, when these stimulants are not contra-indicated; or, in some aromatic syrup, infusion of Walnut Leaves, or milk of Cocoa-nut, which, by the way, forms a useful and agreeable drink for consumptives. A piece of Orange or Lemon-peel, or of Cinnamon Bark, chewed after taking the unmixed Oil, will generally remove its unpleasant taste.

Milk, however, furnishes a large supply of nitrogen to assist in the assimilation of the hydro-carbon or starchy food. Pastries, hot cakes or bread, crude fruits, and other similar articles, must positively be avoided. When the addition of a remedial agent will not render the drink or food unpleasant, nor interfere with the proper action of either, it should be recommended, in order to save too frequent a repetition of doses, which is much dreaded by patients. Starchy diet tends largely to increase the acidity of the blood, while the other hydro-carbon, fat or oil, has an opposite tendency. Full meals should never be permitted; light meals are preferable, and which may be repeated four or five times a day, without overloading or debilitating the digestive organs. Salt may be used freely, as it is of value in all tuberculous affections.

The next important hygienic measure, is, exercise in the open air. If the patient is able to be about, he should endeavor to secure some light business that will require him to travel, and be more or less constantly in the open air, and that will at the same time occupy his mind without requiring too much mental action, or causing any anxiety. Traveling agent, book agent, peddling, etc., are all of this kind, but should be pursued only in temperate climates where the atmosphere, as a general rule, is free from cold and dampness, and where there are no sudden changes of weather. Yet, if he *can* and *will* attend to himself faithfully, and accommodate himself to these changes, by suitable change in clothing, keeping within doors in unsuitable weather, etc., he may even travel in the objectionable climates. For, even with these disadvantages, the travel, change of scenery, open air, mental occupation, etc., are much better than no travel at all. Short, and frequently repeated trips by sea, are advantageous for those only in the early stage of the disease; long sea voyages are to be avoided, as the sea air is too keen, and good diet, good attendance, etc., can rarely be had.—In those cases, however, where this course can not be pursued, exercise should be taken regularly and daily in the open air, and it should be made as much as possible a matter of pleasure or amusement, instead of a task for the preservation of health,—to

accomplish which, agreeable companions should always be in attendance, if possible.

Females may hop, skip, dance about, run, walk, ride on horse-back, jump rope, pursue calisthenic exercises, etc. One of the objects in exercising is, to expand the chest, and give greater capacity for the action of the lungs, for, if the patient keep himself in a position with the body doubled up or bent forward, the capacity of the chest will become diminished by the diaphragm being pressed upward by the stomach, and various unpleasant symptoms will result therefrom. In whatever position the patient may be,—walking, sitting, standing, lying, writing, sewing, reading, etc.,—he should never lose sight of the absolute necessity of keeping himself in an erect posture as much as possible, having the shoulders thrown back, the small of the back curved inward, and the head as straight as possible. Nor is this all, the patient should be enjoined to promote expansion of the lungs by deep inspiration, repeating it three or four times every day, for from five to twenty or thirty minutes at a time. Keeping the mouth a little open, and the body erect, he will inhale gently and slowly, until he expands the chest to its utmost limits, then retaining it there for a few seconds, he will allow it to escape just as gently and slowly as it was inhaled. This not only expands the lungs, but also their air-cells, rendering them more expansible, and, at the same time, causes a larger amount of the air, richer in carbonic acid, to be exhaled. After each deep inhalation and exhalation, before commencing the next, a few ordinary inspirations should be taken, and so continued alternately. The air should be pure and not too cold. If severe pain is produced, the inspiration may be carried up to the point of pain, and then expiration be made; and, it will be found, that eventually the pain will cease, and a full inspiration can be taken. These inspirations are to be taken independent of any medicated inhalations.

It will be found very useful to bathe every night with some warm weak alkaline water, drying with a coarse towel and considerable friction, and then anointing the whole body and limbs with Olive Oil, Cod Liver Oil, or Cocoa-nut Oil. Any tendency to indolence, oversleeping, or sleeplessness must be counteracted, and the hours of sleep should be regulated as much as possible. The bedclothing should not be so heavy nor warm as to cause perspiration or disagreeable heat; bed-curtains should be dispensed with, and the sleeping apartment should be well aired during the day, and be kept dry and at a temperature not to exceed 65° Fahrenheit in cold weather; being careful not to have the air filled with dust, soot, or

ashes, nor sulphurous vapor from burning coal, nor carbonic acid gas from burning charcoal. A wood fire is always to be preferred for consumptives.—All mental cares, anxieties, studies, depressions or excitements must be avoided, though cheerfulness is desirable; moderation in everything that is allowable, is beneficial,—excesses are hurtful. Moderate labor, cheerful companions, healthy diversions, indulgence of hopes, and cheerful disposition, are all conducive to a proper state of mind and body favoring a restoration to health.—Cold air, or rather sudden changes from heat to cold, or cold to heat, as well as damp residences, must be avoided. A sedentary occupation, or one requiring constant sitting, and especially with the body inclined forward, should also be avoided, as well as one requiring continuous standing, constant stooping over, or where the person is exposed to dust or irritating vapors.—The body should be kept comfortably warm all the time; cotton, wool, or fur may be worn, and most especial attention should be paid, in this respect, to the chest, back and feet, but not to the neglect of other surfaces. India-rubber overshoes should only be worn in walking, to protect the feet from dampness; but thick leather, or cork-soled shoes are much better.

As a general rule, a residence in cities is to be preferred to one in the country, the air being less bleak and sharp, and better attendance and remedies being more easily attained; but hotels and boarding-houses are by no means favorable places for the residence of consumptives. Changes of air, or occupations, are to be made when for the better; but care should be taken not to change for the worse. Change of climate in the second or third stages of the disease are rarely of service, and not unfrequently accelerate the progress of the disease. In the early period of the disease, a change will hardly be advantageous, unless a residence be held for several years in a proper climate; and such changes will usually prove more serviceable to those in whom the disease is not hereditary. In my opinion the best climate for consumptives is in the Southern temperate latitudes, as, for instance, in Buenos Ayres, etc.,—and a sanitarium in that or some neighboring place, either on the Atlantic or Pacific coast, in which a proper attention would be paid to the hygiene and therapeutics of the patient, combining diet, exercise, amusements, medicine, etc., would be exceedingly advantageous for persons in the early period of phthisis.

In the second and third stages, or rather when the patients can not bear exposure to changeable weather, the rooms they occupy should be artificially heated, and maintained at the degree of tem-

perature above named; this, though injurious in the first stage, will prove decidedly beneficial in the advanced.—The general hygiene as respects other conditions must be in accordance with the rules named in the first part of the work, as well as with the circumstances, condition, and constitution of the patient.

The therapeutical measures will consist of remedies to remove the tendency to tuberculous formations, to impart strength and vigor to the constitution, and to palliate or overcome urgent symptoms. But, it must be constantly borne in mind, that there are no specific remedies for consumption,—and that the tubercles once formed are rarely, if ever, removed by absorption—though their further increase, progress, and activity may often be arrested by proper treatment; those agents that will benefit one patient will be found to exert no beneficial influence upon others, and, in many instances, will even lose their efficacy among the patients who had been previously benefited by their use. Each individual case will require to be treated according to its peculiarities, the constitution and habits of the patient, and other surrounding circumstances. All depletive and debilitating measures by purgation, diuresis, perspiration, or emesis, must positively be avoided.

The first thing to be done is, to improve the organs of nutrition, and maintain them constantly in as normal a condition as possible. The mucous membrane of the stomach should be carefully attended to, in order to preserve a healthy condition of this organ, and perpetuate a good appetite. For this purpose, great advantage will be found from the use of the following pills: Take of Citrate of Iron and Quinia with Strychnia two drachms, Alcoholic Extract of Aletris, Alcoholic Extract of Black Cohosh, each, one drachm; mix, and divide into sixty pills, of which one is a dose, to be repeated three times a day, or these articles may be taken in solution instead of pill form; and the quantity of the Citrate may be varied to suit the peculiarities of the patient's system. Other preparations, will sometimes be found of value, as named under Dyspepsia, and Chronic Inflammation of the Stomach.

As alteratives, the Iodide of Iron, Iodide of Ammonium, Iodine Pill, Bromide of Ammonium, Compound Syrup of Yellow Dock, Compound Syrup of Hypophosphites, etc., may be used with advantage, according to the influence they exert on each individual case. I have in some instances derived much advantage from one of the following compounds, viz.:—1. Take of Bromide of Ammonium one ounce, Citrate of Iron and Strychnia three hundred and eighty-four Troy grains, Citrate of Quinia one drachm, Water one pint; mix, and dissolve. The dose is one fluidrachm three or four times

a day.—2. Take of Compound Syrup of Hypophosphites four fluidounces, Hypophosphite of Quinia one scruple, Phosphorus Water one fluidounce,* Simple Syrup three fluidounces; mix. The dose is a fluidrachm three times a day, before each meal.—3. Take of Tincture of Bloodroot two fluidrachms, Fluid Extract of Wild Cherry six fluidrachms, Infusion of Liquorice Root one pint, Hydrochlorate of Ammonia two drachms; mix. Half a fluidounce may be given every two or three hours.—4. Take of Greek Valerian Root two ounces, Wahoo, Black Cohosh, each, one ounce, Water three pints; mix, boil down slowly to two pints. Strain, add Gum Arabic half an ounce, Rock Candy one pound, Extract of Liquorice four ounces, good Cider Vinegar twelve fluidounces; heat till all is dissolved, and when cold add Tincture of Tolu, Tincture of Opium, Tincture of Catechu, each, four fluidounces. The dose is half a fluidounce three or four times a day. This is also useful for cough and early diarrhea.—5. Take of a Saturated Tincture of Black Cohosh, made with good Whisky, Linseed Oil or Sunflower Seed Oil, each, four fluidounces, Honey two ounces, Garlic, bruised to a pulp, two ounces, Loaf Sugar two ounces, Yolks of three Eggs; mix well together. The dose is half a fluidounce three or four times a day. But it must be recollected that if either of these agents disturb the stomach, or, if the disease is advanced so that the patient can not attend to the hygienical measures already referred to, but little benefit can be expected from them.

Certain alterative, sedative, soothing, or healing influences are supposed to be derived from the inhalation of certain vapors; thus, in the Brompton Hospital the following agents, in various combinations, are stated to have been successfully employed in inhalation, as, Chlorine; Creosote; Conium; Benzoic Acid; Hydrocyanic Acid, diluted; pure Deodorized Alcohol; Oil of Bitter Almonds; Nitric, Benzoic, Acetic, and Tannic Acids; Camphor; Balsam of Tolu; Canada Balsam; Iodine; Aqua Ammonia, etc. As examples, I give the following,—1. Take of Nitric Acid twenty minims, Camphor four drachms, Tannic Acid four drachms, pure Deodorized Alcohol six fluidounces; mix.—2. Take of Acetic Acid, Benzoic Acid, Tincture of Conium, each, two fluidrachms, pure Deodorized Alcohol two fluidounces; mix.—3. Take of Iodine, Iodide of Ammonium, each, twelve grains, Tincture of Conium four fluidounces; mix. These inhalations may be employed as explained under Chronic Bronchitis, page 612.—4. Take of Nitre one scruple, common Salt one drachm, Hydrochlorate of Ammonia one drachm,

*Phosphorus water is the water in which Phosphorus is kept in the stores.

Water one pint; mix, and dissolve. Heat a part of this solution, and inhale the warm vapor that arises. In former years I placed considerable reliance on inhalation of vapors in the cure of phthisis, based upon the statements of others, and upon the fact that it appeared a very rational way of bringing remedies in contact with diseased structures. Of late years, however, my confidence in them is considerably diminished; true, I find them useful in chronic bronchitis, asthma, and to relieve certain urgent symptoms in phthisis, (*see* page 612), but as regards the phthisical disease itself they have not appeared to exert any permanently beneficial influence whatever upon it. As a local application to the lungs, in an early period of the disease, I have derived the greatest amount of benefit for the prevention of tuberculous deposits, from the following compound, now published for the first time—it is to be used in conjunction with slow, deep, and prolonged inspirations and expirations, repeated several times every day, (*also see* No. 12, page 613): Take of Chloride of Gold and Soda one grain, Hydrochlorate of Ammonia two scruples, Water five fluidounces; mix, and dissolve. One or two fluidrachms of this solution should be nebulized or formed into a spray, and in this state be conveyed into the air-passages by deep inspirations. This may be repeated once, twice, or thrice a day. The spray from the following mixture will also frequently be found useful in the early stage of the disease: Take of Carbolic Acid half a fluidrachm, Alcohol four fluidounces, Distilled Water two pints; mix, and use about one fluidounce at a sitting, repeating it two or three times a day. But these spray inhalations, though often beneficial, will not invariably be effectual.

Cough is a peculiarly obstinate and distressing symptom: it may be relieved by one of the following mixtures:—1. Take Fluid Extract of Black Cohosh, Fluid Extract of Wild Cherry, Tincture of Bloodroot, each, one fluidounce, Tincture of Sulphate of Morphia (sixty grains to Alcohol one pint), two fluidrachms; mix. The dose is from half a fluidrachm to a fluidrachm three or four times a day, or whenever the cough is very severe.—2. Rub up thoroughly together, two drachms of White Castile Soap, and one drachm, each, of powdered Opium and Camphor. A pill about the size of a pea may be taken whenever required.—3. Take of Tincture of Cannabis Indica one fluidounce, Solution of Sulphate of Morphia two fluidounces; mix. The dose is a fluidrachm repeated three or four times a day.—4. Take of Creosote ten minims, Sulphate of Morphia from one-fourth of a grain to a grain, Water one pint; mix. Heat this solution, and allow the patient to inhale the vapor. This inhalation has frequently relieved cough when other measures

had proved ineffectual. Many other cough remedies have been presented to the profession, some of which are undoubtedly good, while others are useless. But we must be careful not to employ nauseants, or expectorants, in phthisis, as they are not only not required, but are positively injurious in many instances.

The inhalation of Chloroform one part, pure Deodorized Alcohol three parts, will usually relieve cough promptly, or, in place of Alcohol, Tincture of Camphor may be substituted, or, two parts of Petroleum. In some irritable conditions, I have found relief to follow the use of a preparation composed of Tincture of Black Cohosh, Tincture of Gelsemium, each, five and a half fluidrachms, Tincture of Aconite Root two fluidrachms; mix. The dose is twenty minims every hour or two. Bathing the whole surface of the patient's body with warm water slightly acidulated with vinegar, will often prove useful in relieving obstinate cough. Professor Tully observes,—“In all cases allay the cough by some preparation of Opium, in uniform doses, at short and regular intervals, and used continually. The greater the quantity of Opium required in the twenty-four hours, the greater the number of doses to be made, and the shorter the intervals between them. Where much is required, repeat the dose as often as every three hours; where only a moderate quantity is required, repeat the dose about every six hours—never have the interval longer than this. Always give sufficient to restrain the cough as much as possible. If the cough be difficult of restraint, the Opium may be conjoined with some other narcotics, particularly those which act more especially upon the nerves of respiratory motion, as, Conium, Cyanogen, Hydride of Benzoyl, Nicotiana, Aconite, etc.”

Gastric irritability is a frequent accompaniment of phthisis, with nausea, vomiting, and ejection of food. This may frequently be relieved by a mixture of Trisnitrate of Bismuth eight scruples, Mucilage of Gum Arabic two fluidounces, Essence of Lemon one fluidrachm, Lupulin eight scruples. The mixture requires to be thoroughly agitated before taking; the dose is a fluidrachm, as often as required. In some instances, an infusion of equal parts of *Aselepias Incarnata* and *Convallaria Multiflora* will be found to answer; and, in others, a draught may be made as follows: Take of Diluted Hydrocyanic Acid three minims, Trisnitrate of Bismuth ten grains, Mucilage of Gum Arabic, Peppermint Water, each, half a fluidounce; mix. This draught may be repeated three times daily.—Hemoptysis may be treated as named under its appropriate head. A fluidrachm of Hydrochloric Acid added

to a pint of water, and the vapor arising therefrom inhaled, will frequently prove serviceable in small hemorrhages.

Night sweats are a source of much distress and exhaustion; when slight, ten or twelve minims of Elixir of Vitriol in about two fluidounces of Water, may be taken at bed-time with advantage; or, an infusion of Sage and Whiteweed; or, a pill composed of one grain, each, of Lupulin, Tannic Acid, and Extract of Hyoscyamus. In obstinate cases, however, one of the following preparations will be found useful: 1. Take of Oxide of Zinc four grains, Extract of Hyoscyamus four grains, or a sufficient quantity to form into two pills, to be taken at bed-time.—2. Hydrochloric Acid, diluted, ten or fifteen minims, in some water, and repeated two or three times a day.—3. Take of Gallic Acid seven grains, Acetate of Morphia one-eighth of a grain, Alcohol q. s. (a few drops), Syrup of Tolu half a fluidrachm; Water one fluidounce; mix, for a draught to be taken at bed-time.—4. Take of Gallic Acid five grains, Muriate of Morphia one-eighth of a grain, Mucilage, a sufficient quantity; mix; for two pills, to be taken at bed-time.—5. Take of Tannin one or two grains, Opium one or two grains, Simple Syrup a sufficient quantity; mix, and form into four pills, of which one may be given every two, three, or four hours through the day. But if opium or morphia be administered in other medicines, some care must be taken as to the quantity used; if necessary, their use may be dispensed with in these preparations.—6. Take of Oxide of Zinc four grains, Tannate of Quinia ten grains, Extract of Conium five grains; mix, divide into four pills, of which one may be given every two, three or four hours daily.—7. Take of Oxide of Zinc twelve grains, Extract of Conium eighteen grains; mix, and divide into six pills, one or two of which may be taken every night.—8. Take of Gallic Acid twenty-four grains, Extract of Indian Hemp three grains, Extract of Chamomile six grains; mix, and divide into six pills, one of which may be taken every night.

In conjunction with these internal measures, the whole surface of the limbs and body should be bathed or sponged daily with a warm mixture of equal parts of Alcohol and Water, to which some Oil of Cinnamon, Tannin, or fixed Oil of Capsicum has been added; and this bathing should not be pushed so far as to produce rubefaction, but only an agreeable glow and dryness of the skin. In some cases, a bath may be used composed of Acetic Acid, Tannin, and Water. If the body is being oiled every night, these baths may be applied during the day. In many instances, the flannel worn next the body may be previously prepared by moist-

ening it with some stimulating and astringent mixture, and wearing it when dry, as, Tincture of Capsicum, and Tannic Acid; or, a mixture of Capsicum one drachm, Wild Ginger eight ounces, Geranium eight ounces, Canella Alba one pound,—all the articles in very fine powder—may be sprinkled from time to time upon the flannel, being careful when worn, that the patient does not inhale any of the effluvia or powder, and thus irritate the lungs and air-passages.

Diarrhea is a very obstinate and exhausting symptom, for which the Trisnitate of Bismuth will be found available, in doses of from five to ten grains, repeated three times a day; it may be taken in a little Mucilage, or, be combined with three grains of Gum Arabic, and two grains of Magnesia. Other agents have, however, sometimes been of advantage, as, Tincture of Chloride of Iron; or, equal parts of Camphor, Opium, Tannin, and Kino, in doses of three or four grains of the mixture, to be repeated, as required; or, the following will be found of great service: Take of prepared Charcoal two drachms, Tannin, powdered Kino, each, twenty grains, Trisnitate of Bismuth half a drachm, Opium two grains; mix well together. Put this mixture into a pint of Indian Meal Gruel, Rice Water, Barley Water, or Beef Tea, etc., and let the patient take a tablespoonful of the mixture every hour, stirring it up well each time before taking the dose. Where much exhaustion follows the diarrhea, the following injection will be found advantageous: Take of Tincture of Nux Vomica six fluidrachms, Tincture of Prickly-ash Berries eight fluidounces; mix, and add one fluidrachm to half a fluidounce of a strong infusion of equal parts of Solomon's Seal and Golden Seal, for an injection,—to be retained as long as possible, in the rectum. It may be repeated two or three times a day.—The following has often proved useful as an injection in the diarrhea: Take of Solution of Perchloride of Iron five minims, Solution of Muriate of Morphia, ten, twenty, or thirty drops,* Infusion of Elm one fluidounce; mix, for an injection, to be repeated as often as desired, two, three, or four times a day.—A half teaspoonful, every two hours, of a solution of Sulphate of Iron two drachms, in Whisky four fluidounces, has been useful in relieving cough, night sweats, and diarrhea, and imparting strength.

Other symptoms must be treated on general principles, being

* We must be governed, in the quantity of morphia employed in this injection, by the amount of opium or morphia administered, from time to time, by mouth.

careful never to oppress or embarrass the stomach—endeavoring to counteract and overcome, as far as possible, all the various and diverse morbid symptoms of the case, of whatever nature they may be, by such remedies so managed as will accomplish it the most effectually without producing at the same time any undesirable effects.—The preceding measures are especially applicable to the early stage of phthisis; in the advanced periods, they may be persisted in as far as practicable, and according as the patient's condition will permit; perhaps they may thus occasionally prove advantageous,—but, in the latter stages of the disease, palliative measures, to relieve urgent symptoms, are generally all that we will be enabled to adopt.

CHRONIC PLEURITIS.

Chronic Pleurisy may be a primary affection, or, it may result from a subacute pleuritis, or, occasionally it may be preceded by the acute form of the disease. Sometimes it comes on secondarily during the progress of some other maladies, as, of the lungs, liver, stomach, peritoneum, etc. It is more commonly observed among persons of feeble constitution. It is attended with *empyema*,—a profuse effusion of fluid of a serous, sero-puriform, or sero-albuminous character.

The *symptoms* of chronic pleurisy are not always well marked, and, indeed, are sometimes so mild, that even when copious effusion is present, the existence of the disease will not be suspected. In other instances there will be occasional sharp pains, or “a stitch in the side,” occurring generally during inspiration, and often more or less soreness or tenderness upon pressure, or upon moving the arm of the affected side. Sometimes, although there is no dyspnoea, yet the patient will find himself incapable of singing, talking, or reading aloud for any considerable time. The general health may continue unaffected, and without any loss of flesh or weight; and, in some cases, there will be a slight, hacking cough, with or without expectoration. Fever is not generally present, but when it is, it usually appears at night.—When the symptoms are more marked, there will be a hacking cough with or without expectoration, the latter being often very profuse; dry, vague pains in the chest, sometimes quite severe; pallor of countenance; emaciation; respiration short and frequent, and increased on the least exertion or mental excitement; loss of appetite; inability to lie on any other than the affected side; dryness and harshness of the skin; rapid pulse; more or less nervous irritability; hectic fever;

and night sweats. Sometimes the effusion is so great as to produce a manifest protrusion of the intercostal spaces, and even a displacement of the heart, or a curvature of the spine.

However obscure the general symptoms of chronic pleurisy may be, its physical signs are well marked, though modified considerably, according to the duration and amount of the effusion, and the changes undergone by the pleura and lung. Percussion will elicit flatness at the lower and central parts of the lung, or at the side of the thorax, with a marked sense of resistance, and a decrease in the elasticity of the walls of the chest; the flatness will sometimes vary in location upon the patient changing his position, and may frequently be observed, in front, on the opposite side of the sternum; at the apex there may be a tympanitic sound, sometimes having an amphoric character, and occasionally the bruit de pot fêlé. On the unaffected side, the sound on percussion will be very clear; occasionally an emphysematous sound will be observed. The intercostal spaces may be enlarged and protruding, even to convexity, and on pressure, fluctuation may frequently be observed. The affected side does not respond to the respiratory act as fully as the sound side. Auscultation detects an absence or suppression of the respiratory murmur at the lower, central, and lateral parts of the chest, and sometimes over the whole of the side; a bronchial, or broncho-vesicular respiration is frequently observed over the compressed lung; occasionally friction sounds may be detected. Vocal resonance is augmented at the apex of the lung, and occasionally bronchophony, and even pectoriloquy, have been present. The beatings of the heart may also be heard in parts at a distance from this organ. The respiratory murmur of the healthy lung is more intense than natural, and at times much harsher. Vocal fremitus of the affected side is absent. In the interscapular region, as well as in other portions of the affected side, bronchial respiration will be noticed, and, if bronchial dilatation be present, there will also be bronchophony.—Ægophony is seldom present, unless during absorption of the effused fluid, when a gradual shrinking or retraction of the walls of the chest will occur; the affected side becoming flattened, giving dullness on percussion, and a feeble respiration. (*See Note, page 539, sections 24, 30, 31, 32, 33, 35.*)

Chronic pleurisy may be complicated with tubercular phthisis, chronic pneumonia, cancer, melanosis, etc., which are very difficult to detect. The disease must be carefully discriminated from hydrothorax, pericardial effusion, abscess in the walls of the chest, emphysema, and pneumothorax, hepatic or splenic enlargement, tumor within the chest, etc.

The *prognosis* of chronic pleurisy is always unfavorable, and especially so when occurring in enfeebled or strumous systems, when complicated with other lesions, and when hectic fever and night sweats are present, together with scanty urine and œdema of the extremities. Sometimes the disease is cured spontaneously by an absorption of the effused fluid, which generally occurs gradually, the distended side becoming contracted and flattened; and the recovery is more or less complete according to the reduction that has been made in the size and functions of the lung by the previous lesion; being seldom so complete in adults of advanced age, as in the young. At other times the effused fluid may give rise to ulceration and perforation, making a passage through the lungs into the bronchial tubes, from whence it is coughed up; or, it may form an opening through the thoracic parietes, and be discharged externally. Usually, where the chest contracts, the patient is subsequently liable to lesions of the respiratory organs, and an enfeebled or cachectic state, which may end in dropsical or tuberculous affections.

Dr. Williams observes that, "pleurisy is dangerous not from its affecting the blood generally, but from the effects of the local effusion oppressing the lung and otherwise interfering with respiration. The dangers from effusion are not much to be dreaded if that effusion be not very copious, or, if being copious, it is simple."—"It is important to keep in view the effects of considerable effusion, not only in oppressing the lung and interfering with its expansion, but in making pressure on the heart and great blood-vessels."—"The quality of the effusion may be a source of danger as well as the quantity. When the effusion is of a purulent character there are several dangers. There is the chance of purulent absorption; the depressing influence of pent-up matter on the system; and the tendency of the effused fluid to penetrate and make its way through various organs. Other evils may flow from the effusion of plastic lymph. The formation of supple adhesions may not be practically very troublesome; but where caco-plastic lymph is thrown out, contraction occurs, and often gives rise to displacement, obliteration of vessels, and other lesions of serious and inconvenient character."

The *pathological appearances* met with are, thickening of the pleura, which becomes dull and loses its polish and smoothness; false membranes of different forms arising from the throwing out of a gelatinous or albuminous exudation or lymph, and which is susceptible of organization, having blood-vessels running through it; various adhesions of the pleura, which may be soft and easily torn, or, may be changed into a cellular tissue, and, sometimes, even into

a fibrous, cartilaginous, or osseous,—tubercles may also be frequently observed in them. The effused fluid in the pleural character may vary in amount, as well as in appearance,—being colorless, or, yellow and clear, or, containing albuminous flocculi,—or, it may be turbid, tinged with blood, or, resemble jelly, etc. The lung of the affected side will also present appearances according to the degree of compression it has received from the effused fluid. It may be compressed into a very small space and be situated upward in front of the vertebral column; its lobes may be adherent; its parenchyma inelastic, almost bloodless, and without crepitation; there will be adhesions between the lung and pleura; and, sometimes, an effusion into the lung itself. Occasionally, tubercles may be observed in it.

The *treatment* of chronic pleurisy consists in adopting means to diminish or overcome irritation, to promote absorption of the effused fluid, and to sustain the strength of the system. The Compound Tar Plaster should be applied over the diseased region, and a free discharge be kept up by it, for several weeks, if the patient can possibly bear it. It may be applied intermittently, or, alternately upon one-half of the affected side of the thorax, and then upon the other, and should be continued, if the patient's strength will permit, until the pain has been permanently removed, and considerable absorption of the effused liquid has taken place.

To facilitate absorption by stimulating the absorbents, the Bromide or Iodide of Ammonium may be administered internally; or, the Compound Syrup of Stillingia with Iodide of Potassium; or, a solution of Hydrochlorate of Ammonia one hundred and twenty-eight Troy grains, in Fluid Extract of Wild Cherry half a pint; the dose is half a fluidounce three or four times a day.

Cough may be relieved by some of the means already named under Bronchitis, Phthisis, etc. The surface of the body should be bathed daily with some stimulating fluid, and, in drying, considerable friction should be employed so as to produce a glow of heat all over the surface. The bowels should be kept regular, but active purgation must be avoided, as it will be found to produce too much exhaustion; diuretics, and especially those of a stimulating character will be found to answer a much better purpose, as, Queen of the Meadow, Buchu, Pipsissewa, Trailing Arbutus, Button Snake Root, Devil's Bit, Horseradish, Spearmint, etc. The Compound Infusion of Parsley, will be found very useful.—The patient may move about if he is able, and if no irritation is thereby produced; otherwise, he must be kept quiet; and in either case, he should not be allowed to expose himself to cold, sudden atmospheric changes, damp night air, or to too great an amount of exercise. Riding in the

open air, in clear weather, but not to produce fatigue or jar the body, will prove advantageous.

When the effusion is so great as to threaten suffocation, or does not yield to the remedies employed, the operation of paracentesis thoracis has been performed. Although there are obstacles to the universal success of this operation, still it has been followed by cures. The operation, if performed at all, should not be delayed too long, and the spot selected for the puncture will depend upon the situation of the effusion, a complete absence being first ascertained, by auscultation and percussion, of all signs indicating proximity of the lung in the part fixed upon for the puncture. In cases of doubt, an exploring needle may be used at first; to determine the presence of fluid in the cavity. The part usually chosen is, the upper edge of the sixth rib, posterior to the digitation of the serratus major, depending, however, upon the pointing of the fluid. The most eligible sites for the operation are, between the fourth, fifth, sixth, and seventh ribs; and, after the operation, the abdominal and thoracic parietes of the affected side should be pressed upon in order to promote the removal of as much fluid as possible. The operation is described in works on Surgery. After it has been effected, counter-irritation by dry cupping and rubefacients, and tonics, as, Tincture of Chloride of Iron, and nutritious diet, must be employed to complete the cure. The use of Chaissignac's drainage pipe, has also been highly spoken of, for the removal of the effusion. (*See Am. Jour. Med. Sciences*, April, 1852, page 320, *On Pleuritic Effusions and Paracentesis*.)

CHRONIC PNEUMONIA.

Chronic Inflammation of the Lungs is a disease not frequently encountered, more especially its simple form, in which the iron-gray and indurated lung is produced; it is much more frequent in what has been termed its scrofulous or tuberculous form, wherein tubercles are ultimately developed. Chronic Pneumonia very rarely exists as a sequel of the acute form; or, it may exist as a complication of other lung diseases, as, bronchitis, pleuritis, tuberculosis, etc., or of organic disease of the heart; or, it may exist as an original and independent disease.

The *symptoms* greatly resemble those of phthisis, as, cough, expectoration, dyspnoea, accelerated respiration, and quick pulse, and which are augmented on the least exertion. The cough, as well as the expectoration, will vary in character according to the extent and progress of the disease. There is also a loss of appetite, of strength,

and of weight, debility, irregularity of the bowels, morbid condition of the skin, hectic fever, and night sweats, and the patient may die in a few months from exhaustion, from softening of the lung tissue, or from tubercular phthisis. Occasionally the patient may struggle along for several years, when a chronic pulmonary abscess forms, giving rise to the discharge of an offensive purulent matter which finally wears him out.

The physical signs are those of solidification, being similar to those met with in the acute form of the disease. It is very rarely the case, however, that the patient presents himself to the practitioner until he becomes uneasy or alarmed about his symptoms. As the lung diminishes in volume, there will be more or less contraction or sinking in of the thoracic parietes; a lessened movement of the chest-walls on the side affected. Percussion will detect a diminution of clearness, which, as the consolidation increases, becomes more and more dull, and even flat, with a sense of resistance to the percussion-stroke. Auscultation will discover a weak, harsh, or suppressed respiratory murmur at first, with prolonged expiration, but as the disease advances this will change to a bronchial respiration, and a corresponding development of cough and vocal fremitus, and more or less bronchophony. (*See Note*, page 539, sections 1, 2, 3, 6, 7, 8, 12, 15, 16, 27, etc.)

We may generally determine chronic pneumonia from *phthisis*, by observing that the dullness on percussion is in the central and lower portions of the lung, while in *phthisis* it is at the apex, and usually in both lungs; by the history of the case, there having existed a prior acute affection of the lungs; and by the patient not being hereditarily liable to *phthisis*. Hemorrhage is not so apt to be present in pneumonia, although the expectoration may sometimes be tinged with blood from a bronchial affection. Again, the general symptoms are not so severe as those of *phthisis*, except toward the fatal termination of the disease.—But, sometimes, we will find it very difficult, if not impossible, to discriminate between the two diseases, as, dullness may be observed in the apex of the lung, with a blowing respiration, moist crackling, and cavernous or gurgling sounds, indicative of tubercle. In this case, hemorrhage is more apt to be present, and also the usual signs of tuberculous disease. Andral states that in chronic pneumonia the upper part of the lung is more frequently affected than in the acute form.

The sinking in of the chest in chronic pneumonia is not so extensive as that in *chronic pleurisy*, being commonly confined to the lower lobe of the lung, or only to the part affected; in *pleurisy*,

this contraction is more general, or involves only the upper part of the chest.

Dr. Williams, referring to some of the ehronic results of pleurisy and pneumonia, observes:—"The most common result is that, the consolidation not being cleared away, deposited matter is left behind, which ultimately undergoes tubercular degeneration. In other cases the result is condensation of the vesicular lung tissue and dilatation of the bronchi. Owing to the condensation of the vesicular tissue, the air does not enter the cells with facility; but the ribs, museles, and motory apparatus of the parietes continue to act with vigor, driving the air into the impenetrable lung tissue. The necessary mechanical consequence of this is, that the air, acting strongly upon the walls of the tubes into which it is impelled, produces dilatation of the bronchi. This condition of condensation of the vesicular tissue, with dilatation of the bronchial tubes, is apt to be mistaken for phthisis. I have formerly pointed out this result of pleurisy and pneumonia, and explained the manner of its origin and its diagnosis.—It is produced, as I have said, in a purely mechanical manner by the action, on the walls of the tubes, of the air which is driven into them, but can not penetrate the impermeable lung. The physical signs resemble in many respects those of phthisis. There is the dense, dull lung tissue, absence of vesicular breathing, pectoriloquy, and tubular, or even cavernous breathing.

"The diagnosis is difficult, but may be aided in the first place by observing the situation. The signs are not at the upper, but at the lower and central parts of the lung, or at the side of the thorax; and the dullness is very considerable. The opposite conditions prevail in phthisis. Then, as to the general symptoms, there may be all this with a good deal of *embonpoint*, and a ruddy aspect of health, which do not comport with so considerable degree of phthisical disease."—"But I should say that I have seen the consolidation undergo tubercular degeneration, and go on to phthisis, ending fatally. Then, too, when the deposit is considerable and unhealthy, and undergoes retraction to a great extent, it may, under a generally cachectic state of the system, end in death, commonly immediately due to dropsy. The expectoration in these cases of condensed lung with dilated air-passages is very commonly offensive. This fetor may be corrected by inhalations."

The *prognosis* of ehronic pneumonia is more favorable in those cases where there is no tendency to tuberculous depositions, where the system does not suffer much, and where the patient is capable of moving about and exercising in the open air, than in an op-

posite condition of things. A diminution of symptoms, with an increase of weight and flesh is favorable; tuberculous signs are almost invariably unfavorable.

The *pathological appearances* will vary, according to the simple or tubercular form of the disease. In the former, the lung will be found more or less atrophied, and presenting red and gray indurations; sometimes the color will be light yellow, dark-gray, or black, or, these several colors may be present, giving a mottled aspect to the lung. Copland states that according to the tissues involved, the hepatization may "assume a granular or oolitic aspect, owing to the thickening of individual vesicles. In some cases, it appears streaked and veined from the hypertrophy of the interlobular septa and cellular tissue around the vessels; in others it is more uniform and darker in color. In this variety, the cellular tissue between the lobules is sometimes thickened to the extent of several lines, and is of a light drab or gray color, like that of miliary granulations, and like those has almost the density of cartilage." Tuberculous formations may often be observed, and when with the solidification there also exist tubercles, and irregular dilatation of the air-cells, the lung will often present a knobby surface.

The *treatment* of chronic pneumonia will consist of counter-irritation over the diseased region by means of the Croton Oil Liniment, or by pustulation with the Compound Tar Plaster; and great care should be taken not to produce exhaustion by any of the internal or external measures that may be pursued. Derivatives and counter-irritation, when not of a depressing nature, are among the most valuable means of treatment. Turpentine liniments to the chest and back, frequently applied, often produce excellent results. In other respects the same medicinal and hygienical measures may be pursued as named under Chronic Pleurisy. In the tuberculous form, or, when the symptoms strongly resemble those of phthisis, the treatment should be the same as advised for this disease. Indeed, the treatment will be, according to the predominance of symptoms, a well selected combination of the measures recommended under Chronic Bronchitis, Phthisis, and Chronic Pleurisy. Inhalations will be found much more serviceable in chronic pneumonia than in tubercular consumption.—The diet must be nourishing, and pure country air, healthful and happy associations, freedom from business and cares, moderate exercise, tonics for debility, chalybeates for anemia, etc, will be found equally as important as the other curative means employed by the medical man.

Pulmonary Œdema or *Œdema of the Lungs* may exist as a primary affection, and is frequently developed in the course of various organic lesions of the lungs, heart, liver, and kidneys. It is also associated with dropsies of other parts. In nearly all fatal pulmonary diseases, in mitral disease, in cardiac hypertrophy, and in Bright's disease, it is very frequently present. The malady consists of an exudation of a serous fluid into the cellular tissue between the pulmonary air vesicles, and into the cells themselves, giving rise to a slight increase in the size of the affected lung; when the infiltration occurs suddenly, causing death, it has been termed *serous apoplexy*. The *symptoms* are cough, difficult breathing, and expectoration of a frothy serum, which are more or less severe, and are much aggravated by exercise. In advanced cases there will be an inability to lie down on account of the difficulty of breathing it produces. Percussion gives a more or less dull sound over the infiltrated lung, an absence of the vesicular resonance, and a marked increase of resistance of the walls of the chest to the percussion stroke. Auscultation detects fine bubbling or the sub-crepitant rale, sometimes a crepitant; a vesiculo-bronchial, or bronchial respiration; and a feebleness or absence of the respiratory murmur.

The *pathological characters* of the disease are, an increase in the density and weight of the affected lung, which imperfectly collapses on opening the thorax, and which is of a pale-grayish, or yellowish color; it does not crepitate, but retains the indentation caused by pressure; when it is divided, a colorless, or yellowish, transparent fluid, frothy from the presence of air-bubbles, exudes in abundance. The *treatment* must be based entirely upon the pathological conditions giving rise to the œdema, and the particular symptoms that may present themselves. No precise mode of treatment can be laid down. Dry cupping, diuretics, and turpentine liniments, are among some of the means to be employed.

Pulmonary Gangrene, or *Gangrene of the Lungs* (*Necropneumonia*), is always the result of inflammatory action, and is more apt to occur in persons of broken-down constitutions, and of intemperate habits, as well as among those whose blood is impure. It may be diffused or circumscribed; the former being more apt to occur in the upper lobes of the lung; the latter in the inferior, and varying in size from that of a pea to that of small orange.

The *symptoms* are dyspnœa, pallor of countenance, quick pulse, excessive prostration, hemorrhage, and emaciation. But no diag-

nosis can be formed from them. The characteristic symptoms are a violent, convulsive, suffocative cough, and the expectoration of a green or brown matter, sometimes accompanied with a discharge of blood; both the breath and the expectoration are insupportably fetid, rendering the apartment in which the patient remains very repulsive. Dr. Williams states that a peculiar feature of the disease is, that when the abominably offensive expectoration has accumulated for a short time in the sputorium, it acquires rather a pleasant odor, resembling very nearly that of the cowslip.

The physical signs are dullness on percussion, being proportioned to the extent of the disease, and scarcely, if at all elicited when the gangrene is confined to a very small space. Auscultation will give, according to the stage of the disease, and over the affected portion of the lung, absence of vesicular murmur, bronchial respiration, augmented vocal sound, bronchophony, mucous rales, gurgling or cavernous sounds, and pectoriloquy. A sudden gangrenous odor, with the appearance of sloughy pulmonary tissue in the expectoration, is almost always due to gangrene. (*See Note*, page 539, *section 26*.)

The *pathological appearances* will be somewhat variable; previous to the sloughing the pulmonary tissue may be solidified. Edema and inflammatory exudation may be present, as well as an emphysematous condition of some portion of the lung; there may also be evidences of bronchitis; and softened lung tissue with one or more cavities containing an offensive, purulent matter. Adhesions of the pleura, and of the lung, and false membranes lining the cavities may also be observed.

The *treatment* consists in supporting the strength by Bark, Wine-
whey, nutritious diet, and other tonic measures; diminishing irritation by Opium, Opium and Camphor, or other sedatives; administering internally forty to sixty minims of Dilute Nitro-hydrochloric Acid several times a day, in some Glycerin; or Chlorate of Potassa with Bark, or Quinia, or Baptisin. And having the patient to frequently inhale the vapor of Chlorine; Creosote; Creosote and Chloroform; fumes from Coffee while being roasted; or other antiseptic vapors.—Cures have been sometimes effected by half-teaspoonful doses, repeated every four hours, of Solution of Chlorinated Soda, in conjunction with inhalations of Oil of Turpentine, to relieve cough, etc.;—teaspoonful doses, repeated three times a day, of Compound Tincture of Cinchona; or, of a mixture of Cod Liver Oil half a fluidounce, Syrup of Superphosphate of Iron one fluidrachm; mix for a dose, to be repeated three times a day,—counter-irritation over the affected side,—and generous diet, with

wine or porter.—Inhalations of the fine spray of diluted Carbolie Acid, and the same agent administered internally, have likewise been of benefit.

Melanosis of the Lung is a malignant affection characterized by the presence of a morbid production, of a black or blackish-brown color, and is sometimes associated with other morbid productions, as, carcinoma, fungoid disease, etc. Most commonly other parts of the body, besides the lungs, are affected with it. Its *causes* are unknown.

The *symptoms* are obscure at first; there may be impeded respiration, emaciation, cachexia, anemia, dropsical effusion, dyspnœa, purplish appearance of the face, and physical signs of consolidation. At an advanced stage, there is abundant expectoration, which is streaked with blood, or may contain some of the black matter. Death is produced from compression or obliteration of the large vessels and bronchial tubes, and by destruction, ulceration, etc., of the adjoining tissues. The melanotic product may be met with in irregular masses, in small dots or points, in thin, unequal plates, or in small nodules; what is termed the “tuberiform” variety of the disease is the most commonly observed,—it consists of smooth, irregular, or tuberculated tumors, varying in size from that of a pin’s head to that of an orange, and which are of a globular, ovoid, or pyriform shape. The black matter may be either encysted or non-encysted. At a very early period the black matter is deposited in a fluid state, but becomes more consistent from absorption of its liquid parts; but it may be washed out of the tissues containing it. It colors the fingers black, is without any marked odor or taste, readily unites with water or alcohol, and slowly undergoes putrefaction when exposed to the air or kept in water. It is supposed to be the coloring matter of the blood highly carbonized. There is no positive means of diagnosing the disease. As it is an incurable disease, the only *treatment* will be to give tone to the minute capillary system by means of Tincture of Chloride of Iron; give strength and nourishment to the general system by good diet, Compound Syrup of Hypophosphites, etc.; and to arouse the energies of the system by well-regulated exercise, and other hygienical measures heretofore referred to. The symptoms as they occur will require to be treated on general principles.

Cancer, Cysts and Hydatids, and Calcareous Concretions, are occa-

sionally met with in the lungs, as well as, *Cancer, Ulceration, Serous Cysts, Cartilaginous, and Osseous deposits* in the pleura, but as there are no positive symptoms or physical signs, by which either of these affections can be diagnosed during life, and no specific rules for their treatment, save "general principles," this notice of them is deemed sufficient.

CHRONIC DISEASES OF THE DIGESTIVE SYSTEM.

UNDER this head will be included chronic diseases of the mouth, œsophagus, stomach, intestines, peritoneum, liver, spleen, etc.

The principal affections of the *mouth* are, the various forms of stomatitis, which are more commonly met with among children, and which seldom assume a chronic character, unless complicated with some disorder of the digestive organs. These affections may be limited to either the palatine arch, the gums, the tongue, or the cheeks, and occasionally the whole of the lining mucous membrane of the mouth will be involved. They may be divided as follows :

1. *Simple ulceration*, in the form of very tender and sensitive superficial ulcers or abrasions, more commonly at the sides and tip of the tongue, which organ is usually redder than natural. They are generally associated with dyspepsia, or some transient derangement of the digestive organs. Regulation of the bowels, a proper attention to diet, and chewing the leaves of Prim (*Ligustrum Vulgare*), will ordinarily be sufficient to cure the ulcerations; if they do not yield to this treatment, they may be touched daily with a solution of Nitrate of Silver.—Sometimes, these ulcers may extend more deeply into the tissues attacked, having clean or foul bases, irregular or regular edges, with or without elevated and hard or callous margins, the result of irritation from rough teeth. The appearance of the ulcers depend greatly upon the condition of the patient and other surrounding circumstances. A proper attention to the teeth, to the digestive functions, and to the general health of the patient, will generally effect a cure. Constant irritation of a simple ulcer, by a rough tooth, may ultimately develop cancerous disease.

2. *Aphthous or Follicular ulceration* is more common among children. They are preceded by vesicles, and the ulcers are small, flat, oval or circular, single or in clusters, with well-defined margins, no elevation nor hardness, but a bright red areola surrounding them, and with smooth, yellowish or grayish, and somewhat sloughy bases. They are always associated with gastric or intestinal disturbance, and are accompanied by the development of a microscopic cryptogamic plant (*Oidium Albicans*), whose roots are implanted in the cel- lules of the affected epithelium. The disease may extend through- out the alimentary canal. The treatment consists in remedying the irritation existing in the stomach or bowels, by means of mild laxa- tives, as, the Compound Powder of Rhubarb and Potassa, etc.; and the local application of one of the following preparations:—A decoction of equal parts of Blue Cohosh and Golden Seal; a dilute solution of Perchloride of Iron; or a solution of Chlorate of Potassa,—and these fluids may also be administered internally. Tonics and alteratives will frequently be indicated, in addition. In some cases, a collutory composed of equal parts of finely-powdered Borax, and Honey; or, of one part of Hydrochloric Acid and ten parts of Honey, will be found successful. Solution of Sulphite of Soda, or a dilute Solution of Carbolic Acid, has also been found efficacious, administered internally, and also employed as a collutory.

3. *Strumous ulceration* is always associated with a strumous habit of body. It is preceded by one or more deep-seated, compressible, elastic, and somewhat tender lumps or tumors in the body of the tongue, which slowly proceed to central suppuration and ulceration, forming a small or large irregularly-defined ulcer, unequally exca- vated, with a thick, unequal margin, a flat, tough base, and a thick- ness and hardness of the surrounding parts. The treatment named under Scrofula will be useful in this disease, with local applications, to the obstinate abscesses, of a solution of Chloride of Gold and Soda, and the use of a nourishing diet.

4. *Syphilitic ulcerations* may be superficial or deeply seated. They may also appear in the form of deep fissures, alone, or accom- panying more defined ulcerations. They may appear at the angles of the mouth, along the edge or upper part of the tongue, the roof of the mouth, and in the throat. When superficial, they are apt to be sore and sensitive; when deep-seated, they are usually preceded by firm, well-defined, inelastic lumps, which soften, and slough or

ulcerate at their centers. The borders of these ulcers are usually irregular, having no redness in or around them, are somewhat firm, and the ulcers are generally indolent. If any inflammation attends, this must be treated first, and upon its removal, the usual constitutional measures for syphilis may be pursued, with local applications of strong Nitric Acid, or, of a mixture of strong Nitric Acid three drachms, Nitrate of Silver ten grains; to be applied daily, or every other day, by means of a porte-caustic of soft wood. (*See Constitutional Syphilis*, page 448.)

5. *Cancerous ulcerations* are occasionally encountered; their treatment belongs exclusively to the department of Surgery,—though apparent cures have been effected in a few rare instances by local applications of Chloride of Zinc, or of Sulphate of Zinc, as well as with some of the preparations named in the Note on Cancer, page 490.

6. *Gangrenous ulceration* is more commonly the result of mercurial action, though supposed by many writers to be due to impure air, bad food, congregating children together, and to occur as a sequel to some of the exanthematous diseases of children, with whom, of course, a mercurial treatment had been pursued. It is sometimes termed Cancrum Oris. There is a tense and shining swelling of one cheek, with a red spot in the center, which is rapidly followed by a deep excavated ulcer, of an ash color, and covered with a brown slough; this is first perceived inside the mouth, and spreads more or less rapidly, destroying the cheeks, gums, etc., in its progress. The breath is insupportably fetid, the saliva putrescent, and the gums white, spongy, and separated from the teeth, or, dark, ulcerated, and gangrenous. The discharge from the ulcers is often very acrid, excoriating parts with which it comes in contact. If not speedily checked, death soon ensues. The treatment consists in keeping the bowels regular by laxative enema, or mild laxatives internally; and restraining diarrhea, when present, by astringent infusions, as, the Tincture of Chloride of Iron, or, Solution of Perchloride of Iron, and sustaining the strength of the patient by beef tea, wine, jellies, ammonia, etc.

Internally, Chlorate of Potassa, in doses of three grains to a child three years of age, may be given in some wine or water, and be repeated every four hours; together with some Tincture of Nux

Vomica, to stimulate the nervous system and prevent the formation of triple phosphates in the urine.

Locally, the surface of the ulcer (having first removed the gangrenous portion in order to reach the healthy tissue), must be washed by a saturated Solution of Sulphate of Zinc, repeating it from time to time as required. Or, strong Nitric Acid may be applied over the whole of the ulcerated surface, making the cauterization complete, and repeating the application every twelve hours, until the gangrenous action is checked. As these cauterizations are very painful, Chloroform, by inhalation, should be carefully employed, and the surrounding healthy parts should be protected from the action of the caustic.

7. *Fissures and Cracks in the Tongue* are frequently troublesome and obstinate to cure, often rendering eating and speaking very painful. Very often they give rise to deep ulcers having an offensive odor. Local applications of Borax one scruple, dissolved in Water and Glycerin two ounces, each, will be found useful; also a strong infusion of Geranium, Golden Seal, and Blue Cohosh, equal parts. Internally, I have found Balsam of Sulphur to be very efficacious. If the general health be impaired, Elixir of Iron and Cinchona, together with a solution of Bromide of Potassium will prove useful.

It must be recollected that, in most cases, redness or rawness of the tongue, either along its sides or over its whole surface, with pain, heat, soreness or tenderness, etc., of the organ, is indicative of some derangement of the organs of digestion, requiring the proper treatment for such derangements. The same may be said of those cases in which the surface of the tongue is covered with a white or brown coat, where its body is pale, etc.—Dr. C. Fleming, of Dublin, speaks very highly of a concentrated solution of Nitrate of Copper as a local application to deep ulcerated clefts in the tongue; the surface of the ulcer should be dried, the application made by means of a piece of soft wood covered with a strand of lamp wick, and then oil should be at once applied so as to cover the application.—Chlorate of Potassa in from five to fifteen grain doses may be given, with other constitutional treatment.

8. *Tumors, Growths, Hypertrophy and Prolapsus of the Tongue*, are sometimes encountered; but they belong more particularly to the department of Surgery.

9. *Cancer of the Tongue* is either of a scirrhus nature, affecting the proper tissue of the tongue, and commencing with a general or partial nodular enlargement, accompanied with darting pains, more or less difficulty in using the tongue, and a constant expuition; eventually ulceration occurs, giving rise to deep excavations of a foul nature. Or, the disease may only affect the surface of the organ, being epithelial in its character, commencing by induration upon the surface, and terminating in a deep ulcer. The extirpation of the organ is the treatment usually advised in either form of cancer, and this, if undertaken at all, should be done previous to the ulceration, and at an early period of the disease before the neighboring glands have become implicated. Cures are said to have been effected by some of the local applications named in Note on Cancer, page 490.

10. *Neuralgia of the Tongue*, in which the pain is very acute, sharp, or burning and darting, without any abnormal appearance of the organ to the sight or touch, if not a premonitory indication of some cerebral disease, may be treated as advised under Neuralgia, page 282. When associated with other symptoms pointing to paralysis, apoplexy, etc., the treatment recommended for these affections must be pursued.

11. *Elongation of the Uvula* may be the result of repeated catarrhal inflammations, or, it may be due to relaxation of the fauces, as is often observed in follicular pharyngitis. It may also be present in chronic diseases of the air-passages, also in phthisis. It seldom occasions any uneasiness unless its free extremity comes in contact with the base of the tongue, the epiglottis, or surrounding surfaces, when it gives rise to a tickling sensation in the throat, a dry, irritative cough, a sense of uneasiness in the part, or, as if a foreign body was in the throat causing more or less constant efforts at deglutition; sometimes there will be a roughness of the voice, a tendency to vomit, or, even a feeling of suffocation. It is by no means necessary to truncate this organ in every case where it is elongated, as has been too much practised, heretofore, by medical men. When it is associated with digestive disorders, chronic faucial affections, or maladies of the air-passages, astringents and tonics applied to the uvula (together with the treatment for the primary disease,) will generally effect the cure, as, Alum, Tannic Acid, Tannic Acid and Capsicum, Geranium and Hydrastis, etc..

which may be used in solution, infusion, or ointment. Sometimes Nitrate of Silver, applied locally, will be found useful. If the organ is thickened, indurated, and so elongated as to prove a source of annoyance, it may be partially, but never wholly amputated. But before this is undertaken, attempts to reduce it by applications of the following preparation should be made: Take of Iodine of Ammonium three drachms, Iodide one drachm, Ointment of Rose Water (or Glycerin) three ounces; triturate thoroughly together.

12. *Enlargement or Hypertrophy of the Tonsils* in adults may arise from repeated inflammatory attacks, and is usually associated with chronic disease of the throat; in children, it may follow as a sequence to scarlatina, cold, scrofula, etc. Chalky concretions, and cheesy tuberculous matter, are sometimes observed in hypertrophied tonsils. This affection becomes a serious one, only, when it interferes with speaking, hearing, or breathing, and even deglutition, and when it co-exists with follicular disease of the throat; in which cases, it should be removed by excision or caustic, only, when it presents the interference just noticed. When the tonsils are indurated as well as enlarged, various methods have been advised, as excision, enucleation by means of the index finger, or the careful application of caustic, as, Vienna Paste, Chromic Acid, London Paste, (a compound of equal parts of Caustic Soda and Lime, moistened with a little absolute Alcohol,) and applied about once a week;—as this paste has a strong affinity for carbonic acid, losing its properties by exposure to the air, it should be kept in a carefully stopped bottle. Vienna Paste may remain in contact with the tonsil for ten or twenty minutes,—London Paste not more than five seconds; if, in the application of these last named caustics, some other part is accidentally touched with them, Vinegar must be at once applied upon the spot to arrest and neutralize the caustic action. If the enlarged tonsil is in a state of inflammation, this must first be reduced before attempting its removal by excision or caustic, else serious mischief may result; the same rule holds good with elongated uvula.

In ordinary cases, and when the tonsillar hypertrophy is associated with, or is due to scrofula or tuberculosis, there is no necessity for the above treatment. The Iodide, or Bromide of Potassium, or of Ammonium may be administered internally, together with frequent local applications to the enlarged tonsils, of one of the following preparations: 1. Take of Iodide of Ammonium three drachms, Iodine one drachm, Glycerin two fluidounces; tri-

turate together until dissolved. 2. Take of Perchloride of Iron in solution, Glycerin, each, equal parts; mix. 3. Take of Tannic Acid two drachms, Glycerin one fluidounce; mix, and dissolve. 4. Take of Iodide of Zinc three drachms, Iodine one drachm, Glycerin two fluidounces; triturate together.—When these means fail and the enlargement becomes troublesome, its removal may then be undertaken by caustics or excision.

Small cysts in the tonsil are remedied by puncturing them; *ulcerations* of the tonsil may be treated by applications of Nitric Acid, or, by Tannic Acid, Nitrate of Silver, or Perchloride of Iron dissolved in Glycerin.

13. *Chronic Œsophagitis*, or Chronic Inflammation of the Œsophagus, may occur primarily, or may follow the acute form. The *symptoms* will vary in number and in severity, and may sometimes be so mild as not to attract the patient's notice until serious organic changes have occurred,—especially when the disease is idiopathic. More or less pain and a sense of heat or burning is generally present, which may extend from the upper part of the Œsophagus to any point between this and the eighth or ninth dorsal vertebræ; sometimes, it will be experienced only at the inferior part of the pharynx and posterior to the glottis; at other times it will be felt back of the sternum and ensiform cartilage. The burning sensation may exist more or less constantly, or, it may only be experienced for an hour or two shortly after each meal. Not unfrequently the patient will complain that a sensation is experienced as if a tense cord, or a foreign body was in the Œsophagus in one of the points above named. In other cases, a soreness or tightness will be felt under the sternum or between the shoulder-blades. Dysphagia is often present. Deglutition will augment the severity of these symptoms, especially in the advanced stage of the disease; and when the affection is located in the inferior portion of the canal, more or less hiccough is apt to be present. Substances, when swallowed, may give rise to cough, and are frequently regurgitated or ejected by vomiting. Eructations of an acrid character, or of a ropy fluid nature; short cough; frequent hawking or spitting; relaxed uvula; constipation; dyspepsia; a feeble, irritable pulse; emaciation, etc., may also be present. Chronic laryngitis frequently co-exists and sometimes masks the affection of the Œsophagus.

Chronic inflammation of the Œsophagus, though a rare disease, is always a serious one, and especially when it attacks those of

debilitated, strumous, or broken-down constitutions. It may be caused by cold, rheumatism, improper use of ice or iced drinks, obstinate dyspepsia, ingestion of stimulating, irritating, or corrosive substances, abuse of emetics, habitual use of alcoholic fluids, tight lacing, and frequently exists as a sequel of some eruptive disease. It may terminate in resolution, or in thickening and induration with a more or less strictured condition, or, in ulceration.

The *treatment* consists in regulating the bowels, skin, and kidneys, overcoming dyspeptic or other co-existing affections, and the internal use of agents that will act upon the walls of the tube, as, for instance, teaspoonful doses of a mixture of Soluble Hydrastin half a drachm, Iodide of Ammonium one drachm, Glycerin three and half fluidounces; to be swallowed slowly, and the dose repeated three or four times a day. Or, Hydrastin and Wayne's Cimicifugin may be used. Soluble Hydrastin, Hydrochlorate of Ammonia, Geraniin, Bromide of Ammonium, Aletridin, etc., may also be used in various combinations. And, sometimes, much benefit will be derived from a mixture composed of Powdered Golden Seal one ounce, Powdered Cubebs two drachms, Sulphur half an ounce; of this ten or twenty grains may be taken in a little water, repeating the dose three times daily.—Counter-irritation is always advantageous; the Croton Oil Liniment may be applied two or three times a day over the painful or burning points, or over the breast, epigastric region, and between the shoulders; or, a liniment composed of Croton Oil half a fluidrachm, Rectified Oil of Amber two fluidounces; mix. But the best and most effectual method of counter-irritation is by means of the puncturing instrument, to which the uncouth and jaw-breaking name of *dermabiotokon* has been given, and which should be freely and frequently applied over the breast and along the cervical and dorsal regions of the spinal column.

14. *Stricture of the Œsophagus* is of two kinds,—spasmodic, and permanent or organic. Spasmodic stricture, or spasm of the œsophagus occurs in nervous and excitable persons, especially among those who are subject to digestive derangements, spinal irritation, and disorders of the reproductive functions. The principal symptoms are, a difficulty or inability to swallow, pain and a sense of tightness in the affected locality, troublesome respiration, sometimes amounting to a suffocative feeling, and more or less anxiety. The attacks may occur periodically or irregularly, usually appear and disappear suddenly, and sometimes come on

while the patient is in the act of swallowing, and with such force and suddenness as to violently project the fluid or solid from the mouth. They also vary in severity and duration. The *treatment* consists in proper attentions to the digestive, renal, and cutaneous functions; counter-irritation to the spinal column; removal of the exciting cause; antispasmodics; and such hygienical and therapeutical measures as are advised in Hysteria and Reflex Paralysis. In some instances a solution of Nitrate of Silver passed into the œsophagus by means of a probang, will afford prompt relief.

Permanent stricture of the œsophagus is much less common than the spasmodic variety. It may be a result of acute or chronic œsophagitis, or it may be due to some morbid malignant condition of the walls of the tube; injuries and acrid or corrosive applications to the tube may also occasion it. The abuse of alcoholic drinks is said to be a frequent cause. It may occur at any age, and is more generally seated in the superior extremity of the œsophagus, at some part posteriorly to the cricoid cartilage; though it may be located at any part of it. Usually, but one stricture exists in the tube.

The *symptoms* are, at first, some transient difficulty in swallowing, with a sense of uneasiness in some part of the œsophagus; as the disease advances, the difficulty of swallowing increases, especially when solids are swallowed,—deglutition becomes slow, difficult, and painful, and the solid will frequently be felt lodged in the tube, passing, after a longer or shorter time, as if forcibly thrust through a narrowed passage. Finally, nothing but fluids will be able to pass into the stomach. In cases where the stricture is seated low in the tube, the portion above the stricture becomes very much dilated into a pouch or expansion, in which the food is retained for a longer or shorter time, and is then ejected by regurgitation, which is sometimes accompanied with a choking cough. With these symptoms there may be dyspnœa, spasm of the œsophagus, a sense of constriction in the canal, pain, soreness, expectoration of viscid mucus, flatulence, gastric acidity, constipation, palpitations, debility, emaciation, sensitiveness of the surface to atmospheric changes, despondency and mental anxiety, exhaustion, and death. But a person may live for many years with this disease, and then die of some other, especially when it is not associated with a malignant condition.

The disease may be readily detected by a careful examination with a gum elastic œsophageal bougie, which should be carried through the stricture in order to determine its extent. In spasmodic stricture solids are much more readily swallowed than

fluids; in permanent stricture the reverse of this occurs, fluids being more readily swallowed than solids.—It must be remembered that, even when the stricture is located at the inferior part of the tube, the patient will be apt to refer the more urgent symptoms to its superior extremity. (*See Nervous Dysphagia*, under *Chronic Gastritis*.)

Permanent stricture of the œsophagus presents a thickening and induration of the mucous lining membrane of this tube and the subjacent cellular tissue; the muscular tissue is rarely implicated, except in severe cases. This thickening occasions a narrowing of the passage, which may occupy only one side of it, or, more commonly, the entire periphery, forming a kind of ring, the aperture of which gradually diminishes in diameter, as the thickening progresses.

The *treatment* consists in an attention to diet and other hygienic measures; in restoring the general health and removing digestive derangements; and the careful introduction of bougies for the purpose of dilating the strictured part. The bougie should, at first, be introduced every four or five days, then every two or three days, and at last every day, increasing its size from time to time as the stricture yields, the same as in urethral stricture, allowing it to remain in the stricture each time, from one to three or four minutes. The bougies may be anointed with Glycerin, in which some Iodide of Ammonium, Bromide of Ammonium, etc., has been dissolved. All irritating applications must be avoided, lest the thickening process be advanced instead of arrested. The stricture having been overcome, ever afterward the patient should be very watchful of his general health, and should continue to repeat the introduction of the larger bougie, every two, four, or six months, as may be required.

The œsophagus is liable to other affections, some of which may be ascertained by means of the laryngoscope, but most of them are rare, very obscure in their symptoms, and have to be treated entirely on general principles; they are, *Ulceration*; *Congestion*; *Softening*; *Perforation*; *Cartilaginous*; *Osseous*, and *Cancerous Degeneration*; *Polypous growths*; *Paralysis*; *Hemorrhage*; *Gangrene*, etc.

CHRONIC GASTRITIS.

Chronic Inflammation of the Stomach may follow the acute form, but, in many instances, it may exist independently of any previous acute attack. The disease is often confounded with dyspepsia, and when this mistake occurs, if the usual treatment for the latter dis-

ease be pursued, much injury may be thereby accomplished. Chronic gastritis is, however, frequently accompanied with indigestion.

The *symptoms* of chronic gastritis are various, in many cases the only symptoms experienced will be irregular appetite, an uneasy sensation or a weight in the epigastric region, shortly after eating, and an increased redness of the body of the tongue. In others, several of the following symptoms will be present :

More or less distress, weight, fullness, distension, constriction, tormenting heat or burning, or pain is experienced in the region of the stomach, especially after eating ; in many cases, pressure upon the epigastric region will produce a sense of soreness or pain, which may sometimes be so severe that the least pressure will cause the patient to cry out ; the neighboring parts are not affected by similar pressure, unless the intestines participate in the chronic inflammation. Not unfrequently, spontaneous pains, more severe than those produced by pressure, will be experienced in the region of the stomach ; and it is by no means uncommon for patients who have no spontaneous pains, or, very obscure ones, to be suddenly seized, either without any attributable cause, or after an ordinary meal, with severe pains in the epigastric region, and which continue for half an hour, an hour, or even all day. In other cases, instead of pain, there will be a sense of gnawing, of weight, of craving, of sinking, or of epigastric burning, the patients complaining that this is the hottest part of the body ; with many, the ingestion of food and even of drinks determines a sensation of scalding, as if boiling water had been introduced, or else, as if "the food passed over a sore." The pains may be acute, dull, or lancinating, often shoot into the neighboring parts, and have their constant seat under the cartilages of the false ribs, being either fixed or alternating from one side to the other. Sometimes the whole abdomen is the seat of spontaneous pains ; at other times, the anterior part of the thorax, at which point there often exists a very distressing sense of constriction with oppression and anxiety, which is probably due to sympathetic propagation of the pain from the celiac plexus to the pulmonary. These pains, etc., may exist only when the stomach is empty, or, they may be present or aggravated when food has been taken into the stomach, generally, immediately after a meal, or an hour or two after. The epigastric region becomes tense and painful to any kind of pressure, whether it be a belt around the body, or the mere contact of the shirt. The patient feels his stomach, becomes dejected, incapable of acting ; he keeps as still as possible, dreading to move lest he will have to reject the food by vomiting. Frontal headache, or a disposition to drowsi-

ness, frequently accompanies the gastric distress. In gastric diseases, soreness or pain will frequently be produced by pressure upon the first, second, and third dorsal vertebræ, more especially in cases where the serous tissue is affected.

The appetite is likewise variable; when there is some fever present, and emaciation, the appetite is feeble or lost; but when the malady is of a truly chronic form without any general re-action, the appetite is often very keen, more so than in health. In some instances, the least amount of fluid nourishment can hardly be retained upon the stomach, and it is a matter of astonishment to observe upon what a minute quantity of diet life will be maintained; in these cases solid food, or ordinary quantities of fluids, are almost immediately rejected. Sometimes the appetite is irregular, craving, gnawing, fastidious, or morbid, in which the most inappropriate articles are desired. Frequently, when the most craving appetite exists, a mouthful or two satisfies the patient, or occasions nausea. The thirst is as variable as the appetite, more commonly being augmented. The food retained upon the stomach is more or less imperfectly digested, occasioning acid or nidorous eructations, having the taste of the ingested substances, and which are sometimes so profuse and accompanied with such exhaustion as to be the principal symptom complained of by the patient, who asks to be rid of it at any price. Occasionally, particles of food will also be thrown into the mouth. Frequently a glairy fluid will be copiously thrown up from the stomach, without any particle, taste, or odor of the food or drink taken, and which is sometimes accompanied with a constant and most painful feeling of pyrosis. If there is no vomiting nor regurgitation, a slight ptyalism, evidently due to a minor degree of nausea, will be present. This is the most disagreeable accompaniment of digestion, especially when the fluid secreted is warm.—From the imperfect digestion of food, accumulations of gas take place, which, when passed by the mouth, are sometimes exceedingly offensive.—When the matter vomited is green, it may proceed from the abnormal secretion of the inflamed liver; this organ being often involved in the chronic inflammation.

In most cases the tongue is red, or perfectly natural; in others it has a tendency to dryness; sometimes it is smooth and clean, without presenting any dryness, nor more than natural redness. If the tongue be examined on several occasions, especially at periods when the patient has been without any drink for some time, we will sometimes find it very dry, but becoming moist very readily,—so that this is a very fugitive symptom, readily escaping a superficial and seldom-repeated examination. Frequently this organ will be very

red, or of a vermilion tint, with or without a tendency to dryness; this is a symptom of considerable importance, particularly if, at the same time, either deep and longitudinal fissures run through it, or, it is covered with prominent granulations or papillæ, which are much redder than the organ itself. Among those who have not been addicted to alcoholic drinks or the use of irritants, as well as those in whom the disease manifests itself without any attributable cause, from individual predisposition, from night watchings, from exhaustion, the result of insufficient alimentation, from a too sedentary life, from repeated pregnancies and suckling, or from severe mental troubles, the tongue is often tapering instead of being broad, is covered with a white or yellowish coat which is more marked toward its base, and bright red and granulated at its apex. In such cases, there is almost always an existing complication, either nervous, gastralgic, hypochondriacal, neuralgic, or, a general neurosis. Again, in other cases, the tongue will be covered with a coat of greater or less thickness, beneath which the redness of the organ will be very marked, and, in these instances, the tongue is frequently indented by the teeth; sometimes, this coat will only be observed in the morning, disappearing during the day. As a consequence of the state of the tongue, there will be an acrimonious or clammy taste, with dryness, roughness, or astringency, and which is communicated to the pharynx; at other times, there will be an unpleasant taste in the mouth, or a vitiated taste. Ordinarily, the gums are healthy, but sometimes they are red, congested, or soft, spongy, and readily disposed to bleed; this state may be complicated with aphthæ, or, muguet, when the inflammation is very intense, or else toward the end of the disease, when the result is about to prove fatal. In many cases, there is a difficulty of deglutition due to slight inflammation of the pharynx and œsophagus; this symptom is not constant, and usually disappears under the use of demulcents; but sometimes it is very obstinate, leading the patient to believe that his disease is an angina instead of a gastritis.

Chronic gastritis is frequently accompanied with cough; generally, this cough is dry, and comes on by jerks, and consists of a sudden, slightly noisy expiration, without expectoration, occurring, as it were, without the patient being aware of it, he paying little or no attention to it; it is not preceded by the inspiratory effort, by which, in an ordinary cough, the patient prepares to expectorate. At other times, it may be much more severe and noisy, manifesting itself in paroxysms somewhat like the cough of pertussis; again, it may present all the characters of a bronchial cough, with mucous

expectoration. The pharynx, fauces, œsophagus, or larynx may be in an irritable condition, and frequently occasion the cough; and sometimes a fit of coughing will be followed by retching or vomiting. This cough seldom remains during the whole course of the gastric disease; it appears, disappears, and usually follows the phases of increase or diminution of the gastric inflammation; and if the disease becomes aggravated, the bronchial symptoms frequently increase in severity. Cases, proving fatal, have occurred in which the bronchial affection, with sibilant rales, dyspnœa, cough, and expectoration, being more annoying and wearisome than the gastritis, has appeared to be the principal malady, and which, although having appeared a long time after the stomach disease, had drawn off the attention from this latter organ,—this may happen more especially when the gastritis has not been noticed from the first. In some instances, the external symptoms of phthisis are present, and after several months, death occurs.—It is by no means uncommon to observe the ejection of food by vomiting followed by a relief of the cough.—In an advanced stage, the extremities become cold, emaciation ensues more or less rapidly, the patient becomes hypochondriacal, and may linger out a term of years in constant misery.

There are very numerous shades in the symptoms and characters of chronic gastritis, according to which the general circulation is more or less affected. Generally, the symptoms are confined to the stomach; the pulse remains calm, the skin is cool, the urine clear, the sleep tranquil, and the strength, the embonpoint, the color of the face, undergo no change; the chronic disease reacts with difficulty upon the organism, so as not readily to communicate an abnormal impulsion to it. But it is not always so; sometimes, either from a certain predisposition, similar to that which occurs chiefly among sanguine subjects in whom the inflammation comes on from excesses in the quantity and quality of the food, or, from the violence of the inflammation, the pulse increases. If the tongue be abnormally red, the pulse will be found small, tense, and thread-like, and between eighty and ninety beats or more in a minute. Usually, however, with the exception of debilitated and emaciated cases, it presents a width and flexibility, although imparting a peculiar sensation of abruptness to the finger. There will be periods of the day when the pulse and the skin will be in a normal condition, but the circulation will become accelerated after a meal,—the arteries will beat forcibly, being often felt by the patient; the skin becomes moist, and thirst occurs; the same phenomena happen during the night, or after a slightly prolonged

exercise. At the same time, there is apt to be a feeling of general debility, drowsiness, or disorder in the head; the urine is high-colored, scanty, unnaturally hot on passing, and gives an abundant reddish deposit on standing; sometimes it is pale, turbid, and yields phosphatic deposits, instead of urates. Either an excess of urates, or of phosphates, or, crystals of oxalate of lime, are usually present. Leucorrhœa, in females, often appears simultaneously with the chronic gastritis.—When the stomach alone is affected, constipation, either persistent or occasionally alternating with slight diarrhea, is present.

Chronic gastritis may exist a very long time, even for years, without the patient losing the appearance of good health. It is only when the fever or inflammation increases, that the patient emaciates, with change in the countenance, the complexion becoming cadaverous with the cheeks highly colored; and when the disease takes this unfavorable turn, it is seldom limited to the stomach, but extends to other organs, as, the liver, intestines, peritoneum, bronchi, etc.—Pure uncomplicated gastritis is not so frequently met with as when complicated with enteritis,—the “gastro-enteritis” of authors. Enteritis limited to the small intestines, is very rare; that limited to the large intestines or “colitis,” is very common. The enteritis that accompanies gastritis may appear simultaneously with the latter, or, it may come on at a longer or shorter period after the gastritis has manifested itself. Then, in addition to the symptoms already named as proper to the gastritis, there will be a troublesome diarrhea, alternating with constipation; the quantity and quality of the stools being seldom natural. When the disease takes a more favorable turn, the stools become more frequent and less copious; they are consistent, but soft and yellowish, are not accompanied with the tenesmus of the more marked diarrhea, and have no feeling of heat, scalding, or acidity. The diarrhea in gastro-enteritis presents several varieties; in the more severe degree it may be as if purulent, mixed with blood, or else composed of a dark or blackish watery fluid, in which is contained round and hard fecal matters, (*scybalæ*), and of a fetid odor. Sometimes the diarrhea is very liquid with abundant mucosities, which have been compared to the scrapings of the intestines; or else, with flakes resembling fatty matter. In other instances, the matters passed are composed of half-digested food. Frequently yellow or yellowish stools will alternate with white and liquid ones. I have known patients to discharge from one to three quarts of a white, watery, more or less offensive matter, followed in an hour or two by an apparent healthy stool, and continuing this

daily for several months, without any debility being occasioned therefrom, or other unpleasant symptoms. Frequently, however, colicky pains will be experienced in various parts of the abdomen. Pressure is painful, sometimes on one point, sometimes on another; it is often general, and not limited to the epigastric region, as in simple gastritis.

The *causes* of chronic gastritis are many; it may occasionally follow the acute form of the disease, and frequently succeeds febrile diseases, as, small-pox, scarlatina, typhoid, typhus, etc., and more especially when the already enfeebled stomach, during convalescence, is overexerted or irritated by an excess of food thrown into it. It is very frequently produced by intemperance in eating and drinking, by excessive venery, masturbation, and by the improper employment of emetics and cathartics. Some individuals have a strong predisposing tendency to the disease.—Sometimes the cause is obscure. The affection is more common over forty years of age, and is more especially met with among the intemperate in drinking or eating. It is often associated with ulcers in the stomach.

The principal phenomena of chronic diseases of the stomach, are, inflammation, pain, augmented secretion of fluids or gas, vomiting, dyspepsia, or difficult digestion, and anorexia, or disgust for food. These symptoms, being more or less predominant according to the peculiar nature of the case, and occurring consecutively, or existing simultaneously with the same disease, have more or less attracted the attention of observers. Some of these have considered the increased secretion of fluids as the principal cause of the morbid condition; others have attributed it to the very abundant excretion of gas; a third class to inflammation; a fourth to gastralgia, etc. As a general rule, with the exception of the chronic inflammation, these symptoms are the effects and not the cause of the gastritis.—Certain of the symptoms of chronic gastritis and gastro-enteritis resemble those of other morbid conditions in which these affections are absent, and it is of importance to the practitioner to be enabled to establish the *differential diagnosis*. The principal affections to be discriminated from each other, are the following, viz.:

1. *Gastric derangement*, in which the tongue is large and coated with a yellowish-white fur, the taste is bitter, appetite lost, especially a disgust for meats, feeling of weight and fullness at the stomach, nausea, and vomiting of yellow and bitter matters. If the derangement extends to the intestines, colic, borborygmi, swelling of the abdomen, and alternation of constipation and diarrhea are present. But in gastritis we find in addition to the above symptoms, red spots on the tongue, or else a uniform red-

ness with a tendency to dryness, the tongue pointed, thirst, pain on pressure over the epigastrium, and more or less acute spontaneous pains. If the inflammation has extended to the intestines, there will be alternations of obstinate constipation and diarrhea, with tenesmus, spontaneous pains, as well as upon pressure over the abdomen, together with the symptoms heretofore named as characterizing inflammation of the stomach and intestines.—The progress of the disease will also give indications, as the symptoms of gastric disturbance are generally limited to several days or weeks, rarely to several months, while those of chronic gastrointestinal inflammation persist a much longer period.

The causes of these two maladies equally assist in the differential diagnosis. The gastric disorder is produced by a sedentary life, the use of indigestible food, or of bad quality, cold moisture, and generally by any debilitating cause; while gastritis more frequently proceeds from excess of food, spices, alcoholic drinks, constitutional or acquired plethora, drastic purgatives, a sedentary life with succulent food, and generally by excitants.—When there is any doubt regarding the true nature of the disease, or when both elements are combined together, as sometimes happens, we may be obliged to establish the differential diagnosis by observing the effect of treatment, as to whether sedative and demulcent measures produce a better influence than emetics, laxatives, and tonics.

2. *Gastric Cancer*, in its early stage, is difficult if not impossible to determine from gastritis. In cancer, except when located at the cardiac orifice, a tumor is generally present, and may be detected during the progress of the disease, especially if there be considerable emaciation. The presence of the tumor in the epigastrium; the severe lancinating, radiating pain, scarcely at all affected by food in the stomach; the frequent vomitings of the alimentary substances; the coffee-ground looking vomit; and hemorrhage,—are pretty good indications of cancer of the stomach, a disease that rarely reaches two years, and generally but one. In chronic gastritis there is no tumor; but pain and soreness at the epigastrium increased by food; sometimes vomiting, but seldom, if ever, black or coffee-like grounds, but as described heretofore; and but little hemorrhage, if any; and the disease may be cured, palliated, or remain for a long time. The presence of gastro-enteritic symptoms, with clammy mouth, loss of appetite, laborious digestions, thirst, severe epigastric pains, colics, diarrhea, feeling of numbness in the limbs, slight febrile attacks without vomiting or tumor, or with frequent vomitings of food,—remaining persistently for a long time in an individual who has passed his forty-fifth year and who has had

up to this period a good stomach, should dispose us to suspect the presence of a cancerous degeneration.

3. *Gastric Ulcer*, the same as cancer, is difficult to diagnose in its early stage from gastritis. In ulcer of the stomach, the symptoms, at the commencement, resemble those of gastritis, but the prominent ones, are, the pain and the vomiting. There is no epigastric tumor; the pain frequently intermits, is greatly increased by the presence of food, but diminishes as this is digested; the pain is not lancinating, but may be a dull soreness, a burning, or a gnawing sensation, and is augmented under pressure; vomiting may or may not be present; profuse hemorrhage from the stomach is common, much more so, than in cancer, with paleness and debility. It may exist for an uncertain period.

4. *Gastro-intestinal Neuroses*. The principal phenomena are dysphagia, cardialgia, flatulency, vomiting, pain, and dyspepsia; these may exist isolated or combined, and may all complicate chronic gastro-enteritis. We must endeavor to determine when they are subordinate to a gastro-intestinal inflammation, for which purpose they will now be considered separately.

a. In *Nervous Dysphagia*, patients experience a great difficulty in making the alimentary bolus descend into the stomach; during the deglutition there is a sense of constriction at the throat, as if there existed a morsel which could not pass down. Usually, the appetite is good, and it seems to the patients as if they could eat considerable, but as soon as they have taken a few mouthfuls the whole is arrested in the throat, the face becomes much colored, a severe pain is felt under the sternum with a sense of oppression, of choking, prostrating the patient as completely as if he had been laboring beyond his strength. In the intervals between meals these phenomena are absent, and the patients affirm that although they can not eat, they feel well. At the same time they are very fearful, it seems to them like eating thorns, they carefully examine their dishes in order to remove the harder substances, limiting themselves to soups and soft articles of food, and, notwithstanding, either while drinking or eating, they will be attacked with a spasm, a sensation so painful that they fear suffocation. They are often such victims to their fears that they eat hardly anything, and become greatly emaciated. Nervous dysphagia often lasts a very long time, and presents frequent alternations of apparent cure and of spasms which prevent nearly all swallowing; it may persist for months or years, and then suddenly disappear without any appreciable cause. It occurs among nervous persons, those disposed to be anxious about their health, and who unnecessarily alarm themselves concerning it.

Dysphagia associated with chronic gastritis is rather seldom to be met with, and has a regular progress; it is not manifested by transient spasms followed by a readiness in swallowing, but by a habitual difficulty of swallowing with a sense of choking as if the food remained in the throat; there is frequently exspuition of mucosities in the morning and at the end of a meal, with rejection of particles of food, especially of bread. This dysphagia is more frequently the result of a true pharyngitis, because the irritating substances which have acted on the stomach, as, liquors, spices, etc., have also exerted an influence upon the pharynx. Sometimes a slight cough will be observed, the voice somewhat changed in quality, with traces of chronic inflammation, and especially granulations of the pharynx. The general constitution is different, instead of a nervous condition with tendency to hysteria and hypochondria, we will notice a plethoric constitution; the patient relates his symptoms without exaggeration and without any particular alarm, simply complaining of a difficulty in swallowing, without thinking of any danger of choking. The disease disappears gradually, but never so suddenly as in nervous dysphagia.

b. Nervous Vomiting. When there exists an obstinate vomiting, unyielding to ordinary measures, the first thing to be done, is to be assured that it is not sympathetic with pregnancy, or with any morbid condition of the uterus, brain, liver, or kidneys, as is frequently the case. These causes being absent, and the vomiting recognized as idiopathic, it must then be ascertained whether it be due to cancer, simple ulcer, or softening of the stomach, or, to poison; or, whether it be nervous and due to chronic gastritis.

Nervous vomiting must then be established by exclusion, that is, when we can recognize no other appreciable cause that will explain it in a satisfactory manner; it is, par excellence, the idiopathic vomiting. It may be considered as due to a morbid exaltation of the nervous system of the stomach, so that this organ rejects as injurious to it, all ingested substances. There are cases in which this morbid exaltation is perfectly appreciable; thus, without any traces of fever, without loss of appetite, the tongue being clean, and the urine clear, the patient experiences great thirst without any heat or burning in the stomach,—and the ingestion of any substance, whether fluid, or solid, instantly provokes the vomiting. There is frequently excessive pain upon pressing over the epigastric region, appearing and disappearing with a singular rapidity. This form of vomiting may last many months, causing great emaciation, and resisting every medicine administered for its removal; and it has likewise been permanently

cured, with a rapid return to health and strength, merely by properly influencing the patient's mind. Quinia, Belladonna, Cimicifuga, Stramonium, Aletris, Scutellaria, epigastric counter-irritation, cold douches to the back, tepid baths, regularity of bowels, attention to the skin, and easily digested food in very small quantities, are the means to be employed.

Nervous vomiting may be distinguished from that produced by gastritis, by observing, in the first, an absence of inflammatory symptoms, a clear and naturally red tongue, and limpid urine; in the latter, the tongue is abnormally red, or with red points, or dry; epigastric pain is more continuous and does not cease abruptly; the vomiting is not so obstinate, it does not occur with all ingested substances; and food or mild medicines are much better supported, and do not determine acute pain. The vomiting ceases gradually, and does not disappear suddenly and without a return, as sometimes occurs in nervous vomiting; besides, diarrhea, febrile action during the night, red and lateritious urine, symptoms which reveal the presence of inflammation, are often observed. Nervous vomiting is more frequent among the young, especially young females; the vomiting of gastritis may occur at any age, and in either sex.

c. *Cardialgia*; under this name is here meant those pains, usually acute, that are felt in the region of the ensiform cartilage, shooting toward the sternum or one of the sides of the chest, and frequently accompanied with a flatulent or gaseous noise. In ordinary instances, the diagnosis of *cardialgia* is combined with that of *gastralgia*; but occasionally the pain is only felt at the moment of swallowing, and is absent during the interval between meals. It seems that each mouthful of food, that each draught of fluid descends with difficulty, is arrested at the region of the ensiform cartilage, and passes onward from this region with severe pains, feeling as if the substances were passing over the surface of a sore. This suffering continues for some time after the meal, then wholly ceases to re-appear at the next meal. These symptoms appear to establish the inflammatory character of the disease; however, they may be nervous or spasmodic, or else be due to a simple congestion and disappear in a few hours or days.

d. *Flatulency*. In the majority of cases of chronic gastro-intestinal affections, gas is developed in the stomach, often in enormous quantities, and escapes by the mouth with a convulsive singultus over which the patient has no control, and is usually accompanied by a more or less severe burning eructation; sensations of choking, and of difficult respiration, with unpleasant feelings in the limbs,

are likewise experienced, and, sometimes, the flatulency proves extremely annoying to the patient. The flatus is almost always insipid and inodorous, which distinguishes it from the acrid eructations which accidentally occur in cases of indigestion.—When the gas is developed in the intestines, it gives rise to more or less swelling of the abdomen, with dull, noisy rumblings. These abundant secretions of gas may be due to a want of nervous energy, but they may also originate in a chronic inflammation of the digestive canal, as manifested by a very red, pointed tongue, which preserves the impression of the teeth; pain in the epigastric region; good appetite; very difficult digestion; sensation of heat or burning along the œsophagus; and lateritious deposits in the urine.

e. Idiopathic Dyspepsia is more especially the result of sedentary living, of great mental exertions, of a diet not varied enough, and composed of amylaceous articles which do not sufficiently stimulate the stomach; and is frequently cured by a country residence for a month or two, conjoined with exercise and a cessation of mental labors. In these cases, the tongue is usually pale or whitish, often covered with a mucous coat, there is no abnormal thirst, no desire for food, and without any marked distaste, nausea, sometimes vomiting of ingested substances, heaviness of the stomach without acute pain, difficult stools, pulse slow and feeble, skin rather below the natural temperature, heaviness of the head, sometimes headache, general prostration, and an inability to labor constantly without producing extreme weariness.—These symptoms enable us to establish the differential diagnosis between idiopathic dyspepsia and chronic gastritis. In the latter, the tongue is red and dry; there is a distaste for food, or else a very keen appetite; digestion is painful; there is thirst; some febrile action; and the cause of the affection is likewise of a different character.

f. Gastralgia is characterized by acute, lancinating, or dull pains, by cramps, a sense of burning, heat, smarting, twisting, constriction, etc., in the region of the stomach. It often changes its character, giving sensations of twitchings, vacuity, insatiable appetite, or contusion in the epigastric region. With some there is a fearful anxiety which returns every little while, the patients seeming to apprehend that some misfortune is about to happen to them. These peculiar symptoms, their mobility, their rapid succession, are presumptive indications of neuroses, and will serve to distinguish the gastralgia from gastritis, in which the pain is more continuous, less subject to momentary absences, and does not present the changeableness of that of simple gastralgia. Besides, the condition of the

tongue, the pulse, the urine, digestion, and general constitution will aid in confirming the diagnosis.

There is a mild form of chronic gastritis that I have frequently encountered, which is often attributed to indigestion, or to hepatic torpor, and which may continue for many years without its true nature being suspected, finally proving serious. It is more common among corpulent persons, though spare habits are by no means exempt from it; and those who use freely of spices, of articles not readily digestible, of alcoholic drinks, etc., as well as those whose diet is principally of an amylaceous character, and who are of sedentary habits, are more especially subject to it. In most instances, it is associated with an extension of the low grade of inflammation into the intestines. The symptoms are, a redness of the fauces; slightly increased heat of the mouth; lips dry; the patient frequently picking off the dried mucous covering of the under lip; tongue slightly redder than usual, or natural; a sense of heat in the epigastric region, and sometimes along the œsophagus, accompanied with thirst, and which is much relieved by cold drinks; sometimes, stimulants or carminatives will temporarily relieve the heat or pain, should the latter be present; at about the usual meal-time the appetite is frequently very intense, and is accompanied by a sensation of heat and gnawing in the epigastric region, the patient feeling hardly disposed to wait until the meal is fully prepared,—and the first mouthful or two immediately relieves all these urgent sensations; a bad, clammy taste in the mouth in the morning; an indisposition to exercise; slight irregularity of the appetite, and of the bowels; frequent attacks of gastric acidity; flatulency; itching of the surface, especially at night; urine changeable. Certain substances when eaten, either distress the stomach very much, or if the intestines be also affected, cause a sudden attack of diarrhea, the discharge being watery, light yellow, more or less slimy, of a very offensive odor, and frequently accompanied with pain,—this is the case, especially, when eggs, custard, milk, certain fruits, beer, ale, etc., are swallowed. In some cases, the flatus and diarrhea are very annoying and painful, coming on at unexpected and undesirable times, with strong tenesmic pains in the rectum, which are relieved upon the evacuation of the usually fetid flatus, or of the fluid, very offensive fecal matter.

These symptoms, it must be borne in mind, are, at first, often so slight as hardly to attract attention of either the patient or physician, may continue during the whole year, and may persist for many years without being very much increased in severity. Sometimes, they may be present for a few days, then, after a few weeks or

months, re-appear, and so continue, *very gradually* becoming more and more severe and troublesome, and, as a general rule, are attributed to dyspepsia, or biliary derangement,—and I have no doubt but that fatal diarrhea, and even cholera, has resulted from the treatment pursued in these cases, from a mistaken idea of their true character. The symptoms are, however, more apt to manifest themselves, so as to more particularly call the patient's attention to them, during the hot seasons, and especially in the early summer months; the patient finds his bowels to "get out of order," having diarrhea, in some instances, from the most trivial causes, or from the slightest changes in diet, and which diarrhea often obstinately resists the usual treatment, or may, in some cases, be at once checked by a draught of raw brandy and peppermint. When called to cases of this kind, if the practitioner will carefully investigate them, he will ascertain that, in each instance, the patient has been more or less subject to the symptoms heretofore named for one or several previous years.

The *treatment* I have found the most successful in these cases, is an especial attention to diet and regimen. Using nutritious diet, easy of digestion, and in moderate quantities; keeping the bowels regular daily, by diet if possible; frequent bathings of the whole surface of the body; moderate exercise every day in the open air; an avoidance of all stimulants, spices, tea, coffee, etc., also of exposures to cold; or to sudden changes of temperature; as well as of all kinds of excesses. A cold infusion of equal parts of Witch Hazel Bark, Solomon's Seal, and Leptandra, should be taken in tablespoonful doses, four or five times every day; sometimes, the addition of an equal proportion of Quassia to the above, will be of service. Ptelea, Hydrastis, Barberry, Sheep Laurel Leaves, Colombo, Chamomile Flowers, and Sassafras, are agents that may be advantageously employed in various combinations with each other, or with the articles named in the preceding sentence. In a few cases, anodynes with or without Trisnitrate of Bismuth, have been useful. In the warm summer months, when not otherwise contra-indicated, cold water poured upon and along the spinal column, will be of great benefit; it should be repeated every morning, immediately after rising. And this course should be perseveringly pursued for several months, in order to effect a permanent cure.

In forming a diagnosis of chronic gastritis, it must be recollected that, as a general thing, if amylaceous and milky food is better tolerated, or disturbs to a much lesser degree the digestive functions, than a purely animal diet, or even meat soups or broths, it is indicative of irritation or inflammation; if, on the contrary, an animal

diet, or meat soups, are better supported, or produce less gastric disturbance than the amylaceous and lactic diet, it is indicative of gastric atony, or of a dominant atonic element co-existing with the symptoms of the gastritis, and for which mild tonics, stimulants, etc., are proper.

The *prognosis* depends very much upon the circumstances attending each individual case. When the malady is recent and uncomplicated, it may be cured in the course of a few weeks; but if it be of long standing, a year or two may be required for the recovery. In the advanced periods of the disease, the prognosis is unfavorable, especially when aphthous ulcerations appear upon the tongue and inside the lips, indicating approaching dissolution. Sometimes the disease terminates in ulceration, softening, or gangrene of the stomach.

However mild the case may be, if the accompanying diarrhea has existed for several months, or even years, a rapid cure will seldom be obtained. The diarrhea should never be suddenly checked, and especially by means of astringents and opiates, for the patient may thereby be greatly injured; for, when suppressed by proper measures, and with much greater reason when suddenly checked by improper means, it is apt to return either without any appreciable cause, or under the influence of the slightest causes, such as, a cold, a slight error in diet, a moral impression, or the production of more than ordinary fatigue. A resumption of the proper treatment will overcome this recrudescence; generally, however, the patient becomes discouraged after several successive relapses. But, the physician should encourage him to rigidly persevere in the necessary treatment, which is, of course, tedious and not pleasant; for in long-standing cases, perseverance alone will be crowned with success,—the intervals between the relapses become more and more lengthy, until finally the relapses will cease altogether. Each set-back will also be less severe, less durable, than the preceding one, and will yield under the influence of less energetic measures. A cure once effected, the patient will at first be able, with prudence, to adopt a course which otherwise would certainly have resulted in a relapse; he will be able to eat nearly every article of food indifferently, and occasionally to exceed the necessary limits, to fatigue himself, and to resist indulgences, which previously would have proved prejudicial to him. But, if the disease is of very long standing, the derangements well marked, the acquired or congenital constitution bad, and if, as is frequently observed, the patient will not confine himself to the proper regimen and treatment, during the necessary time,—if he will not renounce

the habits which are often the commencing point of the disease,—a cure will be impossible, and the various symptoms common to the malady previous to its fatal termination, will successively manifest themselves.

If the symptoms become greatly aggravated, other morbid phenomena frequently become associated with the gastritis, among which may be named hepatic congestion, hepatitis, changes in the biliary secretion, jaundice, etc. When the chronic inflammation is limited to the stomach, we are more apt to observe complications of the liver manifesting themselves, probably because that when enteritis is conjoined with it, the accompanying diarrhea favors the disorgement of the hepatic secretion. In case of gastro-hepatitis, occurring after several successive attacks of simple gastritis, the mouth will be found dry, the thirst more intense, the appetite lost, the constipation obstinate, together with swelling of the epigastric region and tenderness on pressure, pain shooting beneath the hypochondriac regions, sometimes quite severe in the sides, at other times, unchangeable, occupying the right hypochondrium, the iliac region, and often the right side of the chest. When the pain increases, the patient becomes agitated, sleepless, uneasy, lies upon his abdomen, but without the sufferings, cries, and violent agitation met with in true hepatic colic, which his condition somewhat resembles. The complexion is wine colored, the circulation calm, the urine scanty, brownish yellow, and turbid. When symptoms due to the liver are manifested, the patient without being confined to his bed will observe that his complexion is yellow. The icterus will attain its maximum of intensity upon the fourth or fifth day; then the more severe pains diminish very sensibly, or cease altogether; the jaundice is yellow, approaching a brown color; the stools are scant, at times of a saffron yellow, rarely gray, that is to say, the course of the bile as a general rule is not completely interrupted. These symptoms disappear slowly, sometimes in three or four weeks, at others in several months. The least error in diet readily occasions a relapse. When the termination is about to be fatal, after a certain number of relapses, we frequently observe the patients to gradually decline, while symptoms resembling those of what is called adynamic fever, present themselves. When enteritis is associated with the gastritis, there is a want of assimilation of the food, and a morbid change in that which is absorbed; a deterioration of the elements necessary for a proper hematosis is thus produced, from which results, general emaciation, anemia, loss of strength, dry skin, and more commonly, anasarca, with or without peritonitis.

This complication, or rather, this frequent termination of chronic gastro-enteritis demands especial attention, because it presents one of the most alarming forms of the disease under consideration, and also because, we are seldom called to a case of the kind until these symptoms have manifested themselves, and may then be erroneously led to believe that we have only a case of simple peritonitis to treat, or else, be at a loss to determine the cause of the anasarca. The information that may be elicited will show that the commencing point of the symptoms before us was some derangement of the digestive canal, to which attention was not given, either from negligence, or ignorance of their true value, or, because these symptoms often have their origin in habits of intoxication, or of gluttony, which the patient wishes to conceal.

In cases of this character, the gastric symptoms are very manifest; we find the tongue vividly red, often dry, intense thirst, frequent vomitings, loss of appetite, and very obstinate constipation alternating with diarrhea. This form of gastro-enteritis is chiefly observed among individuals who are given to alcoholic drinks, who have almost wholly lost their appetite, eating salted foods, spices, cheese, etc.,—but nothing really substantial. After a longer or shorter time, sometimes a few months, at others several years, from the constant use of such food, the blood, deprived of a great part of its plastic elements, becomes defibrinized; and it is not rare to observe the blood readily escaping, occasioning sero-sanguineous effusions, or, protracted hemorrhages from the anus, the nose, gums, or bronchi. From the same cause, the serous elements of the blood, being in excess, and no longer retained by the normal plasticity of this fluid, become separated and determine those serous accumulations in the cavities and in the cellular tissue, which form one of the terminations of gastro-enteritis.

In some instances, after having existed a certain time, chronic gastritis becomes complicated with headache, attacks of vertigo, and the patient may perish from an apoplectic attack. The frequent repetition of similar cases, leads to the belief that they are not simple coincidences, but bear the relation of cause and effect, and which is of great value in the prognosis. It may be remarked here, that the same causes that give rise to gastro-enteritis, as, alcoholic drinks, high living, troubles, etc., equally induce cerebral affections, and that, in a number of acute or chronic diseases of the digestive tube there are frequent cerebral complications. And there is reason to believe that, when chronic gastro-enteritis is complicated with persistent headache, or attacks of vertigo; when the patient's ideas flow more slowly, and he is more sensitive to

impressions, some organic change of the brain is to be feared, especially softening.

As heretofore observed, cough, and even a severe bronchitis may complicate simple gastritis. But we must never lose sight of the possibility of a tuberculous element, especially if the parents labored under this affection, or if the general constitution of the patient is weak; because, it is by no means rare, after several years of diarrhea with dyspepsia, or of imperfect digestion with symptoms of gastro-enteritis, to observe symptoms of pulmonary phthisis manifesting themselves to terminate the scene.

Gastro-intestinal neuroses frequently complicate gastro-enteritis, and may persist after the inflammatory symptoms are almost entirely removed, so that it will be difficult to distinguish their origin. This is an embarrassing complication, as the practitioner may be misled by the neuroses and administer nerve remedies, instead of those designed to remove the chronic inflammation. But in doubtful and complex cases, where one class of remedies appears to produce injurious or undesirable effects, the administration of those of the other class will frequently be attended with good results. The removal of the inflammatory symptoms may not always be followed by the disappearance of the gastralgia, in which case, the appropriate nerve remedies will be found efficacious.—Other complications may exist, but it is unnecessary to refer to them here.

The *pathological appearances* of chronic gastritis, are somewhat similar to those observed in the acute form, but less marked. There may be a slight redness of the lining membrane, or it may be very pale. In persons of intemperate habits in eating or drinking, it may present a dark-reddish brown color, a slate gray color, or the villous membrane may be blackish-blue, with thickening, induration, etc.; the hypertrophy, when confined to the follicles gives a warty appearance; when confined to the villi, velvety or fungoid prominences may be observed. The pyloric portion is generally hypertrophied also, and is very apt to be the principal seat of the chronic inflammation. Sometimes, portions of the mucous membrane may be softened, broken down, or wholly destroyed; and occasionally ulcerations may be observed. Instances have occurred, in which no organic changes whatever, had been detected on dissection. Sometimes, atrophy will be present; or, a combination of hypertrophy and atrophy,—thus, the muscular coat of the organ may be atrophied, while the submucous cellular tissue is more or less hypertrophied.

In the *treatment* of chronic gastritis, or gastro-enteritis, there

are three very important points, a neglect of either of which will render a cure doubtful, these are,—perseverance in the proper measures; time, for no cure can be made where there is haste, or attempts to cure quickly; and a correct regulation of diet. Wine, alcohol, coffee, tea, spices, and all acrid, irritating, or indigestible substances, must positively be avoided. As drinks, various articles may be allowed, bearing in mind the degree of inflammatory action present, and the influences resulting from the use of the fluids allowed; thus, gum arabic water, rice water, barley water, toast water, arrow-root, buttermilk, whey, lemonade, made without the peel, acid syrups, as of gooseberry, cherry, strawberry, raspberry, etc., or decoctions of the same fruits, when in season and fresh. The syrups made with glycerin will prove less irritating than those with cane sugar. A drink composed by adding a fluidounce of Lemon Syrup acidulated with Lemon-juice or Citric Acid, to a solution of half a drachm of Bicarbonate of Potassa in two and a half fluidounces of Water, and drank while effervescing, forms a very grateful and useful draught; it may be repeated two or three times a day. When the inflammatory action is less urgent, other more nutritious articles should be permitted, being careful, however, to omit them as soon as any unpleasant results follow their use; thus, oysters, tender venison, animal jellies, tender beefsteaks, poultry, birds, etc. A tea of veal, salted, and flavored with some leguminous plants will be found very mild, and easy of digestion; it generally facilitates regular alvine evacuations, and frequently arrests diarrhea, for which it is ordinarily useful; about an ounce of veal may be used with a quart of water. Should the patient have a craving desire for some article of food not considered proper by the physician, it will sometimes be the case that a gradual and cautious use of it will be followed by permanent benefit; but this does not apply to irritating or indigestible articles. Excessive thirst, or a morbid desire for beer, wine, brandy, etc., may often be overcome by gargling ten or twelve times a day with cold water, or acidulated water, by chewing small pieces of ice, and by the use of warm baths. No solid food should be allowed to pass into the stomach until it has been slowly and thoroughly masticated; and the meals should be held at regular hours. Where there is great debility, and the stomach is very irritable, it will be better to have several meals a day, partaking only of a small amount of nourishment at each. Milk frequently occasions nausea, sensation of weight in the epigastrium, heartburn, diarrhea, etc., and should not then be allowed; among those with whom it agrees, clotted milk will also be found beneficial.

Moderate and gentle exercise is allowable where the strength of the patient will permit, and no unpleasant symptoms result therefrom, as, walking, riding, or sailing, etc.,—but violent or long-continued exercise must be prohibited. The society of cheerful persons is always to be preferred. Frequent bathings of the surface with a stimulating and weak alkaline solution, will be serviceable, especially when considerable friction is employed in drying. The patient should sit and stand erect, keeping his shoulders well backward, so that the inferior extremity of the sternum can not make undue pressure upon the stomach; and this position should also be maintained as much as possible when in the recumbent position.

The therapeutical measures will depend considerably upon the symptoms which present themselves; if there be much epigastric heat, dryness of the mouth, thirst, pain or tenderness either spontaneously, or upon pressure over the epigastrium, an infusion of Marsh Mallow and Peach Leaves may be used, adding to each dose, five or ten drops of Tincture of Sheep Laurel Leaves, so that twenty or thirty drops of this tincture may be taken per day, according to its effects. Or, the following may be used: Take of Trisnitrate of Bismuth two or three grains, Opium one-third of a grain; mix for a dose, and repeat two or three times a day. Sometimes, Sulphate of Iron in doses of half a grain, made into a pill with a grain of Extract of Hyoseyamus, or,—in powder with Sulphate of Morphia one-eighth of a grain, Sugar of Milk five or ten grains, and repeated two or three times a day, will prove decidedly beneficial. At the same time, counter-irritation must be applied to the epigastrium, and continued until all the urgent symptoms are removed; in some cases, sinapisms will answer; in others, the Croton Oil Liniment may be required, the Dermabiotokon, or even the Compound Tar Plaster. Frequent bathings, diaphoresis, and diuresis, will be found very valuable adjuncts to the above measures, especially in plethoric or congested conditions. It may be that the disease will not improve under the use of demulcents, sedatives, and counter-irritants, being due to, or associated with, neuroses, in which case tonics, iron, antispasmodics, etc., will be required.—After the more urgent symptoms have permanently subsided, the above-named measures may be dispensed with, and non-stimulating tonics be employed; as, half-fluidounce doses of an infusion of equal parts of Golden Seal and Solomon's Seal; or, of Ptelea; or, of Solomon's Seal and Witch Hazel, which is especially useful in long-standing cases. These give more vigor and energy to the digestive powers, and restore the mucous membrane

to health; other bitter tonics have been employed with advantage, either alone or in various combinations, as, Colombo, Gentian, Dandelion, Aletris, Small Centaury, Chalybeate draughts, etc. The addition of Bromide of Potassa, or Bromide of Ammonium to these infusions, has proven very useful in many cases of long standing, probably by assisting in more quickly removing thickened and indurated conditions, etc.

In some cases, where there is considerable epigastric heat and tenderness, with a shining, smooth tongue, the following pills have proved very useful: 1. Take of Nitrate of Silver ten grains, Subnitrate of Bismuth ninety grains, pulverized Black Cohosh forty grains, Alcoholic Extract of Conium thirty grains; mix, and divide into forty pills—dose, one, three times a day. 2. Take of Oxide of Silver four grains, Alcoholic Extract of Aletris twelve grains, pulverized Colombo, q. s.; mix, and divide into twelve pills—dose, same as the preceding. 3. Nitrate of Silver has also been injected into the stomach by means of a stomach tube having one-eighth of an inch bore, and a number of small orifices at its gastric extremity, so that the fluid may be thrown outward and upward on the walls of the stomach. A solution of one to four grains of the nitrate in three fluidounces of water, may be injected at one time, repeating it every one, two, or three days according to circumstances. It sometimes causes pricking sensations, pains, or nausea and retching, which soon pass off. While using the injections, the patient should be confined to small and frequent meals of milk, adding tapioca to it as he gets better.

An atonic condition will frequently be found to succeed the inflammatory, there being a deficiency of nervous energy of the stomach, for which a degree of stimulation will be required, and to produce which one or more of the following agents may be used: Copaiva, Oil of Tar, Turpentine, Cubebs, Benzoic Acid, etc.,—and which will be found valuable; but great care must be taken not to employ them at any other time, as they will be apt to augment the symptoms. I have derived considerable benefit in these atonic cases, from the use of the following mixture: Take of Fluid Extract of Cubebs four fluidrachms, Mucilage of Gum Arabic one fluidounce, Essence of Lemon thirty minims, Lupulin, Trisnitrate of Bismuth, each, four scruples; mix. The dose of this is a fluidrachm, to be repeated three or four times a day, shaking the mixture well immediately previous to taking it.

The bowels must be kept regular, but all drastic or irritating cathartics must be carefully avoided, as they will tend to aggravate the symptoms. Rhubarb, in doses of from three to ten or more

grains, as may be found necessary, taken in a little water, and repeated three times a day, will frequently answer; or, in cases of acidity, it may be combined with half its weight of Bicarbonate of Potassa, or Bicarbonate of Soda. One gentle evacuation per day, is sufficient—but never to exceed two. Other laxatives may be used, as, Rhubarb and Manna; Senna and Tamariuds; Citrate of Magnesia; or, a mixture of Bicarbonate of Soda and Magnesia, each, fifteen grains, daily. When nausea and vomiting are also present, fluid Magnesia will frequently prove useful, or, the addition of a drachm or two of Carbonate of Magnesia to a pint of Water highly charged with Carbonic Acid, and taken during the morning, one-fourth at a time, repeated every half hour or hour. The addition of Leptandrin, or Podophyllin, to the laxative medicines, will be very valuable in cases where the liver is also involved in the inflammatory action.—Obstinate vomiting is often relieved by dry cupping over the epigastrium.

Diarrhea may be overcome by an infusion of Epilobium; or, by teaspoonful doses, repeated every hour, of a mixture composed of Compound Syrup of Rhubarb and Potassa four fluidounces, Tincture of Prickly-ash Berries one and a half fluidounces, Elixir Paregoric six fluidrachms; mix. In connection with these agents, injections will prove decidedly useful, as: Take of Compound Tincture of Virginia Snakeroot one fluidrachm, Water one fluidounce; mix for an injection, and repeat every hour or two; or, an infusion of equal parts of Solomon's Seal and Witch Hazle, may be injected. In cases of excessive debility, and where diarrhea occurs upon the least exertion, the following will be found a valuable injection:—Take of Tincture of Prickly-ash Berries one and a half fluidounces, Saturated Tincture of Nux Vomica one fluidrachm; mix. To a tablespoonful of an infusion of Solomon's Seal add a teaspoonful of this preparation for one injection, which should be retained in the bowels as long as possible, and be repeated three or four times a day. (*See Diarrhea in Consumption*, page 666.) When the liver or spleen is involved with the gastro-enteritis, White Liquid Physic administered internally, together with the use of the first above-named injection will prove useful in most instances of accompanying diarrhea.

A troublesome cough may be relieved by one of the cough preparations named under Bronchitis, or Pulmonary Consumption.—Muguet or aphthous patches may be treated by Borax Water, Solution of Borax, with Morphia; infusion of Golden Seal and Blue Cohosh, equal parts, etc.—When the liver or spleen participates in the inflammation, there will be spontaneous pains, or pain upon

palpation or percussion, of one side or of both, which may be relieved by the application of a Belladonna Plaster over the part, or, a plaster composed of Soap Plaster, Extract of Cicuta, and Gum Ammoniac. Sometimes, counter-irritation will answer a better purpose.—Flatulency is frequently very annoying; it will gradually pass away as the chronic inflammation subsides. When troublesome it may be relieved by the use of Anise or Peppermint Water, to each dose of which a grain or two of Dioscorein is added. Or, the following will frequently prove useful: Take of Tincture of Prickly-ash Berries half a fluidounce, Essence of Anise two fluidrachms, Dioscorein fifteen grains; mix, and triturate until the Dioscorein is dissolved. The dose is half a fluidrachm in two fluidrachms of an infusion of Pleurisy Root, and repeated as may be required.

Mucous irritation of the mouth and stomach may frequently be benefited by the following: Take of Tincture of Chloride of Iron one and a half fluidrachms, Chlorate of Potassa one drachm, Tincture of Black Cohosh four fluidrachms, Infusion of Ptelea eight fluidounces; mix. The dose is a tablespoonful repeated three or four times daily.

When the disease occurs in intemperate persons, it sometimes happens that no decided relief can be procured, until we permit them the moderate use of wine, brandy, or ale, etc.; but, in ordinary cases, these are not allowable, except great debility is present, in which I have known brandy to be swallowed several times a day, without resulting in any unpleasant effects; still, it must be borne in mind, that all liquors of a stimulating nature are, as a general rule, contra-indicated, being permitted only in cases of atonic conditions of the stomach, or, where this organ has been habituated to such drinks, and even then using them with very great caution.

In cases where, from an absence or deficiency of secretion of gastric juice, the food swallowed acts as an irritant, the use of Pepsin, or Rennet Wine during the meal, will often prove serviceable, the latter in those cases where wine is not contra-indicated.—(*See Deficient Secretion of Gastric Juice.*)—When other organs are involved in the chronic inflammation, they must be treated as recommended under their respective heads, being careful, however, to avoid all remedies or measures that will augment the gastro-enteritic symptoms. I can not refrain from saying here that I have successfully treated many cases of gastro-enteritis with very minute doses of Croton Oil,—to avoid its irritating and purgative influences. One drop dissolved in two fluidrachms of Ether, the dose of which is

from two to ten drops, in some demulcent, and which may be repeated three times a day.

GASTRIC ULCERATION.

Ulceration of the Stomach presents three varieties, which have been termed, superficial, follicular, and perforating ulcer. But it is very difficult during life to form a differential diagnosis; and the symptoms of either variety are less distinctly marked at the early period of ulceration than at a more advanced stage.

Superficial Ulcer may be the result of a subacute or chronic catarrhal inflammation of the gastric mucous membrane, and is characterized by vomiting, pain in the pit of the stomach, pyrosis, loss of strength or great prostration, and sometimes vomiting of blood. The prostration is generally a marked symptom. Not unfrequently the ulceration is associated with phthisis, renal anasarca, cardiac disease, cirrhosis, and pyæmia, which renders it probable that a general diseased condition of the blood may be a predisposing or exciting cause. Vomiting of a coffee ground looking substance has occurred a few days previous to death, in cases following continued portal congestion.

The *pathological appearances* of this form of ulcer are, a congestion of the mucous membrane, especially at the rugæ; destruction of this membrane near the lesser curvature, or, at the pylorus; one or more ulcers, usually more numerous near the pyloric orifice, of various sizes, extending through the mucous membrane, having irregular or rounded margins, and minutely injected or pale in color. The mucous membrane is thickened when chronic irritation has existed; and the gastric follicles are more or less destroyed by the ulceration.

Follicular Ulceration is usually observed in children, though it may occur in adults. When it occurs in children, diarrhea or cholera infantum is apt to be present, with irritability, restlessness, pinched features, and symptoms of severe gastritis; occasionally, there may be vomiting of blood, or of coffee-grounds substance; and sometimes the vomiting of the last-named substance will be the only indication of diseased stomach manifested.

The *pathological appearances* are, minute ulcers studding over the whole of the mucous membrane; these ulcers have irregular margins, extend into the gastric follicles, to a depth equal with the mucous membrane, and are spread over the greater part of the stomach. The mucous membrane may be more or less intensely congested.

Perforating Ulcer, also called *simple*, and *chronic* ulcer, though sometimes it assumes an acute form. It is a common affection, occurring in about two and a half per cent. of the bodies of persons dying from all causes; occurs more frequently in women than in men, in the proportion of nearly two to one; is rarely observed under sixteen years of age; and is usually met with in persons of middle and advancing life, especially after the fiftieth year. Its more common location being on the lesser curvature, the anterior surface, the posterior surface, and the pyloric pouch. It is a rare affection in this country; but in those parts of Europe where it is common, it occurs much more frequently among the poorer classes. The real causes of the disease are not positively known; by some it has been regarded as the result of prior inflammatory action; by others, as the result of anemia, or a local failure of nutrition, not in any degree necessarily connected with inflammation.

The *symptoms* of chronic ulceration of the stomach are, at first, disturbances of gastric digestion, which may lead the patient to suppose he is laboring under dyspepsia; this is followed by uneasiness and pain in the epigastrium, sour eructations, and then nausea and vomiting. Even at this early period perforation may occur and occasion sudden and unexpected death; if it does not occur, more or less profuse hematemesis manifests itself, with anemia and emaciation, and the disease may continue with great irregularity in the symptoms and in their severity, for a few months or even years. The pain and the vomiting are the more determinate symptoms.—The appetite is often unimpaired, the tongue natural or pallid, and thirst absent; the bowels may be regular, sometimes diarrhea, but constipation is more frequently present; and there may be, in many cases, an absence of heart-burn, pyrosis, acid eructations, and flatulence. The countenance usually presents a worn and suffering appearance, quite different from that of the nervous or fidgety look of simple chronic dyspepsia; and the degree of emaciation is generally dependent upon the extent of the ulceration.

The pain is seldom absent, but varies in severity, from a sense of weight to a dull continuous pain, which ultimately becomes severe, gnawing, or burning. It usually commences increasing in severity about from five to ten minutes after the ingestion of food, and continues during gastric digestion. Sometimes it immediately follows deglutition; or it may not come on for an hour or so after a meal; and, in some rare cases, it is worse when the stomach is empty, being alleviated when food is swallowed. Usually, when the contents of the stomach are ejected by vomiting the pain is at once arrested. The pain is almost invariably located in the epigastrium, commonly

in the median line just below the point of the ensiform cartilage, and sometimes to the right or left of this; it is generally limited to a circular area, not exceeding two inches in diameter, and is accompanied by pain in the lower dorsal vertebræ, which may sometimes radiate into the shoulders or down the spine and legs. Very moderate pressure over the epigastrium, usually augments these pains, while rest and the recumbent position alleviate them. The pains are also increased by active exercise, mental excitement, mental depression, fatigue, and improper food. The pain is usually relieved by one position, and aggravated by the opposite one, thus not only giving a clue to the existence of an ulcer, but also to its situation. Occasionally pain may be absent for a longer or shorter time, during which food may be used without occasioning any unpleasant symptoms.

Vomiting is a dangerous symptom; yet it is not always present in this disease. When it is present, it does not generally come on until many weeks after the manifestation of pain. Ordinarily it is of an easy character, comes on when the pain is most intense, and completely relieves it by emptying the whole of the contents of the stomach, consisting of food more or less digested, with or without a quantity of saliva, or, thin watery or viscid mucus, and at times, blood, or bile, in varying proportions. The vomiting appears to be more intense when the ulcer is of large size and long duration.

Hæmorrhage may depend upon various causes independent of ulceration, and can only be considered a valuable symptom when it is grouped with the other symptoms. Habershon, to whom I am considerably indebted in my description of gastric diseases, says: "Unless hæmorrhage takes place we can not with any certainty diagnose ulceration of the stomach; sallowness of complexion, pain, and vomiting, all arise without ulceration in cases of gastrodynia, and irritability of the stomach, sympathetic or otherwise." The hæmorrhage may be profuse, or it may be so minute as to require the aid of a microscope to detect blood in the matters ejected, or in the stools. Abundant or arterial hæmorrhages are more apt to occur after meals, in which cases it is generally preceded and accompanied by faintness and nausea,—and when hæmorrhage has once occurred it is very liable to occur again; the blood may be bright-red if vomited at once, or, if retained for a time before being expelled, it may be partially darkened or clotted. Sometimes, a fatal hæmorrhage may occur, without vomiting, the whole of the stomach and duodenum being filled by a single enormous clot. Among females, amenorrhœa may precede or follow the hæmorrhage, but not always. If the hæmorrhage be not due to the sup-

pression of a natural discharge, if there be no disease of the heart, spleen, liver, or kidneys present, and if the hemorrhage has been preceded for some weeks or months by pain or soreness of the stomach, especially after meals, we have strong reasons for suspecting gastric ulcer, when the bleeding is associated with pain, vomiting, etc. Hemorrhage does not occur in chronic inflammation of the stomach.

Gastric ulcer may terminate by gradual exhaustion; by hemorrhage; by perforation into the peritoneal cavity, producing acute peritonitis ending life in twenty-four or thirty-six hours; or, by inflammation being produced, and extending to the neighboring organs. Sometimes, the disease may remain in a passive condition for a long time, and the patient die of some other malady. Perforation only occurs in about eight of every ten cases.

The *differential diagnosis* between gastric ulcer and chronic gastritis has been already named in the history of the latter affection; its determination from *gastric cancer* is based principally upon the following points: Cancer seldom occurs under forty years of age, while ulcer may occur at any age, especially among young females; cancer is accompanied with severe lancinating pains, seldom affected by food, while in ulcer the pain may radiate but is never lancinating, and is increased by the presence of food in the stomach; in cancer, we most generally observe vomiting, which may or may not be present in ulcer, and the matters ejected in cancer will often be found to contain cancer cells; in cancer, there is great acidity, with symptoms of indigestion, which may be absent or very slight in ulcer; in cancer, hemorrhage is not so profuse as in ulcer, and occurs at a later period of the disease; in cancer, fever is present, but not in ulcer; in cancer there is a hard, moveable tumor in the epigastrium, which is absent in ulcer, unless there be adhesion; in cancer there is a gradually progressing emaciation and debility, while in ulcer there is extreme paleness and debility almost from the commencement; cancer terminates in one year, rarely extending to two, while ulcer may prove suddenly fatal, or last many months or years, or it may get well. In the early periods of these diseases, it is impossible to discriminate between them.* (*See Chronic Gastritis*, 3, page 696.)

*Dr. William Brinton, to whom I am also much indebted for material concerning the history of gastric diseases, in speaking of the pain and vomiting, but without hemorrhage, remarks: "But though these symptoms make up the minimum safe basis of diagnosis, to require them, before permitting ourselves to suspect the lesion, would be a grievous error in practice. To say nothing of those doubtful cases on record, in which the symptoms have not been investi-

“The size of the ulcer may be determined by the constancy of the pain and the severity of the other symptoms. If the pain be slight, and of short duration, and the appetite be good, and vomiting occur seldom, and there be no emaciation—the ulcer is small. The location of the ulcer is determined by the spot in which the pain is felt. If there be much tenderness at the *epigastrium* and *no pain in the back*, the ulcer is most probably on the anterior face of the stomach.” (*Budd.*)

The *prognosis* of gastric ulcer depends considerably upon the duration of the disease, and the severity of the symptoms; it is not necessarily a fatal disease, though it may destroy life in a few days, and again not for thirty years or more. Spontaneous cure occurs in about half the cases; and when a large ulcer heals, the cicatrix often occasions a contraction which seriously affects the shape, size, or calibre of the organ. When perforation or erosion of large arteries occurs, death almost invariably results,—but these lesions can only be suspected, and not determined until after death. Nausea, or vomiting, faintness, great prostration, livid features, feeble pulse, and coldness of the extremities are very unfavorable symptoms. Vomiting, without great prostration, faintness, feeble pulse, etc., and with or without slight hemorrhage, and followed by an alleviation of pain, is a more favorable symptom.

“When an ulcer has perforated the mucous membrane of the

gated during life with sufficient exactitude to lay much stress on their alleged obscurities or deficiencies, a careful study of the malady has convinced me that there is no exact limit to the degree in which it may be rendered latent by the absence or the ill-marked characters of some of these symptoms. Indeed, their slow succession in many cases might alone prepare us for the fact, that vomiting may be limited to nausea or regurgitation, and hemorrhage be so scanty and infrequent as to defy the most frequent and sedulous examination of the matters expelled from the stomach by stool or vomit.

“It is in such cases that we must make the pathology of the lesion in general supply any casual deficiencies in the physiognomy, (if we may so speak), of the case in particular; and must remember that suspicions which fall far short of a definite diagnosis may yet be sufficiently important to dictate the whole plan of treatment. Suppose, for example, that we are consulted by a patient for protracted and severe dyspepsia, which has seriously affected the general health; that we find this dyspepsia especially called forth by proteinous substances, and by hot fluids; that it is associated with pain and tenderness in the epigastrium, and pain in the lower dorsal region, much increased after the ingestion of food, and affected as above described by movement, rest, and posture. In such a case, by treating it as ulcer of the stomach, we may often cure what we can not justifiably diagnose; and may witness a triumph of the art over the science of medicine which the most laborious pathologist would scarcely be sorry to see more frequent than modern research generally allows it to be.”

stomach, it is very difficult to heal; and when cicatrization does occur, unless the ulcer be very small, a deep depression remains, and the lost substance is very imperfectly restored. This is owing to the frequent changes of volume the stomach undergoes from being empty or filled with food; to the constant churning motion that the organ undergoes during digestion; as well as to irritation of the ulcer by the mechanical or other action of ingested substances; and, probably, also, to the action of the gastric juice upon the exposed tissues beneath the mucous membrane, which dissolves and removes the lymph poured out on the bottom of the ulcer,—for it is only by means of this plastic lymph that the lost substance can be repaired and the ulcer heal.” (*Budd.*)

The *pathological appearances* met with in gastric ulcer, vary; in most cases, the stomach presents no marks of disease, except a single deep ulcer on its inner surface. In other cases one or more ulcers may be present, or two ulcers may be fused into one; occasionally, four, five, and six have been found together. The ulcer is usually circular or oval, sometimes elongated, or even zonular so as to encircle the stomach; its size ranges from that of a pea to even four or five inches in diameter. Evidences of slight inflammatory action are observed in the tissues around the ulcer, the membrane forming the margin of the ulcer being swollen, thickened, and indurated, from exudation of lymph into the sub-mucous areolar tissue, as well as into the matrix that surrounds and ensheathes the stomach tubes. The ulcer may extend through the muscular and even through the peritoneal coat of the stomach; its inner aspect is bevelled, or in the shape of a cone, from the opening being large in the mucous membrane, smaller in the muscular, and still smaller in the peritoneal. Sometimes, adhesive inflammation occurs before all the coats of the stomach have been perforated, lymph is poured out, and an adhesion of that part of the organ covering the ulcer takes place with the pancreas, left lobe of the liver, spleen, or other organ in proximity; this may prolong the life of the patient by closing the aperture made by the ulcer, and thus prevent the contents of the stomach from passing into the peritoneal sac. When the ulceration extends deeply, it often perforates a branch of one of the arteries with which the stomach is supplied, occasioning sudden, profuse, and even fatal hemorrhage. Fatal perforation is most common when the ulcer is situated on the anterior wall, or along its lesser curvature. Contraction of the organ is observed in cases of cicatrization of a large ulcer.

The *treatment* of these varieties of gastric ulceration is about the

same; being, at the commencement, or in the milder forms, that which has already been advised for Chronic Gastritis. Two very important points are required in the management of this disease, viz.,—to maintain a state of absolute rest of the stomach, and to nourish and improve the system without irritating or disturbing the gastric malady,—two requirements which it is impossible to fulfill except in a very imperfect manner.

In the fulfillment of these requirements, one of the most important points to be attended to is, the diet. A purely milk diet is undoubtedly the very best that can be adopted, especially where much anemia and debility is present; and great care should be taken that the milk is of good quality, and fresh from the cow, a very difficult, if not impossible thing to obtain in our large cities. Other articles may, however, be used, as Indian meal gruel, oat-meal gruel, tapioca, and other properly selected farinaceous substances, to which there is no repugnance, and which agree with the stomach. In some cases, especially, when the symptoms are not severe, or when a favorable change has taken place, egg-custards, rice-custards, blanc-mange, well-boiled rice, mutton, beef, or fowl broth, finely mashed potatoes and carrots, and similar nutritious forms of food that pass quickly from the stomach, may be permitted.—Rich soups, high-seasoned food, pastries, pickles, salads, and all insoluble, irritating, or indigestible substances must positively be avoided, as well as all alcoholic, vinous, fermented, or other stimulating drinks. The juice of fruits may, however, be used with benefit, as of oranges, lemons, strawberries, raspberries, peaches, blackberries, grapes, etc., to which a small portion of sugar may be added, if desired. In some cases, the juice of muskmelon or of water-melon will quench thirst, and be of service.

The quantity as well as the quality of the food demands attention; the patient should take as much, each time, as he can without causing pain, even though this does not exceed a teaspoonful at first,—and should repeat the small meal as often as compatible with the ease of the stomach, being very careful not to perform any bodily or mental labor during the first hour or two of digestion. As a general rule, but little medicine will be required, if the food be properly regulated. Yet urgent symptoms may be present, or may arise from time to time, that will require some remedial agent, and when this is the case, the medicine should be mixed with the food whenever it can be done without causing a repugnance to the mixture, or, a destruction of the therapeutical virtues of the remedy. And among the medicines that may be thus used, and with advantage during the whole course of the disease, are,

Citrate of Iron and Quinia, and Citrate of Iron and Strychnia. If, notwithstanding all these means and the treatment hereafter named, the vomiting continues, we should allow the stomach to rest for a few days, and rely upon nutritive and slightly stimulating enemata—keeping the patient, in the meantime, in a horizontal position, and as quiet as possible. Sometimes cold food will be better tolerated by the stomach than warm.

If there be considerable irritability of the stomach, this, together with any gastric heat or burning that may be present, may frequently be relieved by the patient chewing and swallowing, every now and then, small lumps of ice. In other instances, the Trisnitate of Bismuth, Conium, Opium, Morphia, weak Solution of Potassa or Soda, Lime-water, etc., will be found serviceable. The Oxide of Silver has also proved beneficial; as well as a small pill composed of Nitrate of Silver one-fourth or one-half of a grain, mixed with half a grain of Opium, or with one-eighth of a grain of Extract of Belladonna, or, in cases of constipation, with Extract of Hyoscyamus. Yet I must confess that in my own practice, I have not derived so much benefit from Nitrate of Silver administered in this way, as the statements of others concerning its efficacy, would lead one to expect.—In conjunction with these internal means, counter-irritation to the epigastrium, and along the lower dorsal vertebræ, will be of decided benefit in most instances, as, Croton Oil Liniment, sinapisms, hot fomentations, Dermabiotokon, and especially Dry Cupping. And these measures will likewise be found very useful in relieving the pain as well as the vomiting. Not unfrequently the vomiting, in cases of gastric ulcer, can not be checked until some leeches have been applied to the epigastrium; being where much local pain is present, aided by the internal use of opiates.

Acid eructations may be prevented by the use of Magnesia after each meal, to each dose of which five or ten grains of Trisnitate of Bismuth may be added. In cases where there is fermentative action, or a development of *sarcinæ*, Sulphite of Soda in twenty-grain doses, or Sulphite of Magnesia, may be administered, alone, or in conjunction with other agents. Pain is best relieved by a pill of Opium, with or without the addition of Trisnitate of Bismuth; or, a bladder filled with pounded ice, applied over the painful part for a few minutes at a time, will give relief. The latter will likewise be of efficacy in case of hemorrhage.

Hemorrhage or vomiting of blood requires the patient to keep in the horizontal posture for some time, as quiet as possible; fasting for a prolonged period; and trying ice cataplasms, as heretofore

referred to. When severe or obstinate, it may be checked in most instances by ten grains of Gallic Acid dissolved in an ounce of Distilled Water by the aid of ten minims of Dilute Sulphuric Acid. Trisnitrate of Bismuth ten or twenty grains, mixed with Compound Powder of Kino five or ten grains, has also proved useful in checking hemorrhage, as well as diarrhea when this is present. Oil of Turpentine in doses of ten or twenty minims, taken in cold water, and repeated according to the urgency of the symptoms, has also been efficacious; Tannin, Alum, etc., have also been advised, but I have never used them.—Anemia requires the use of Iron; but this agent is contra-indicated when frequent vomiting, or excessive and continuous pain, are present. When Iron is given it should always be in a soluble form.—The bowels may be kept regular by enemata; or, by Aloes, or Compound Colocynth pill, used occasionally, which irritate the stomach less than other purgatives.

When perforation has happened, and even when peritonitis has manifested its early symptoms, there is still a chance of cure, or rather of prolonging life, by keeping the patient perfectly quiet, allowing him no nourishment, save a teaspoonful of water or milk occasionally, to assuage thirst, and administering Opium in grain doses every three or four hours. This course checks peristaltic action, and permits adhesions to occur, when life may be preserved for a longer period.—Excessive prostration may be overcome to a greater or less extent by injections and inhalation of stimulants.—Strong, or continued pressure upon the epigastrium, by lacing, tight clothes, or otherwise, must be carefully avoided in all maladies of the stomach, and especially in ulceration; immoderate or severe exercise, and excessive mental emotions, are, likewise, equally to be avoided.

I cured one case of chronic gastric ulcer by the following course: To a pint of Indian Meal Gruel made of equal parts of Milk and Water, one tablespoonful of Compound Powder of Charcoal was added,—and of this a tablespoonful was taken every hour or two, except during sleep. For drink, the patient used an infusion of equal parts of *Spiræa Tomentosa*, *Adiantum Pedatum*, and *Althæa Officinalis*. Orange-juice was used freely. The patient was perfectly free from all pain, vomiting, and hemorrhage, after six weeks perseverance in this treatment. I saw her several years afterward, and she had continued well.

I see no reason why injections into the stomach, in the manner named under Chronic Gastritis, may not frequently be beneficial in gastric ulcerations; using dilute solutions of Nitrate of Silver;

Chloride of Gold and Soda; Tannin; Alum; infusions of Golden Seal, Blue Cohosh, and Geranium; Golden Seal and Witch Hazel, etc. I merely name this as a suggestion, and shall act upon it, whenever opportunity offers.

GASTRIC CANCER.

With the exception of the uterus, cancer affects the stomach more frequently than any other organ; and from its frequency, its fatality, and its difficulty of diagnosis in many cases, it requires an attentive consideration. It is a specific degeneration, belonging to the class of heterologous formations, and is most ordinarily a primary disease,—the stomach being the part first attacked with it. All the different species of carcinoma are met with in the stomach; the most frequent being the scirrhus or fibrous, next the medullary or encephaloid, and lastly the areolar or colloid. They may occur separately, or in combination, being really mere varieties of the same disease, differing chiefly in the relative amount and arrangement of their cells and fibres. The pyloric extremity is the most frequent seat of the disease, the next most common location is at the cardiac orifice, and then along the smaller curvature between the two orifices. The *causes* of gastric cancer are not known, though there appears to be, with some persons, a hereditary predisposition to it. The malady is met with in all classes of society, being rather more common among males than females, more usually occurring after the thirty-fifth year, and destroying life in from six to fifteen months, rarely extending to two years.

The *symptoms* of gastric cancer are at first obscure, being similar to those of chronic gastritis, or dyspepsia,—pain in the stomach, tenderness, flatulence, cardialgia, vomiting, etc. As the disease progresses the appetite becomes greatly impaired, very acid eructations occur, with sometimes ejections of small quantities of food, emaciation, and lowness of spirits,—but the thirst, the tongue, the pulse, and the skin continue about natural. Finally, the pain in the stomach becomes more severe, and of a gnawing, burning, or lancinating character, sometimes being of a most agonizing nature, and generally radiating. The pain is almost always constant, and may be augmented either by a full or empty condition of the stomach. Sometimes a severe lancinating pain is manifested at an early period of the disease. Vomiting also occurs, and is often a prominent symptom, coming on shortly after a meal, and, in some cases, not until several hours afterward; the matters thrown

up are often frothy and fermenting, containing the *sarcinæ ventriculi*. At other times the vomited matters are very sour, consisting of food partly digested, and partly in a state of acetous fermentation, and this may be of a soot-black, or of a dirty-reddish brown, resembling coffee-grounds, from being intermingled with blood; or, a glairy mucus may be ejected, mixed with black or brown flakes, consisting of blackened and altered blood. But any great amount of unmixed blood is seldom observed, except ulceration has taken place, when the hemorrhage may sometimes be profuse. Should the ulceration destroy the pneumogastric nerve, the vomiting may cease entirely. In connection with the above symptoms, palpation or manipulation will at some period of the disease detect an irregular tumor, in or near the epigastrium, and which is a very important symptom; indeed, without the detection of the tumor, in addition to the gastric disturbances, anemia, gradually increasing debility and emaciation, we can not possibly diagnose cancer.

The other symptoms generally observed in connection with those just named are, extreme flatulency; fetid breath or eructations, though not always present; obstinate constipation; gradual emaciation and debility; despondency; a pale, tired, and faded look, the countenance somewhat resembling that of jaundice, or a mixture of the chlorotic and icteric hues; and, finally, increased pain and vomiting, with more or less irritative fever.

The *diagnosis* of gastric cancer is sometimes very difficult, especially when no tumor can be detected; and even then we must be careful not to mistake an enlarged liver, spleen, or pancreas for the malignant tumor. If the disease occurs after the age of thirty-five, with loss of appetite, harassing pains, vomitings in spite of a low diet, and the matters mixed with darkened blood, the emaciation and debility progressing more rapidly than in chronic gastritis, we may strongly suspect cancer; and our suspicions will be verified by the presence of the tumor. Vomiting of blood rarely occurs in cancer until toward the latter period of the disease. In cancer, most cases die of exhaustion within twelve months, and occasionally within two years; in gastric ulcer the disease may exist for many years. Cancer is not amenable to treatment, ulceration frequently is. (*See Chronic Gastritis*, page 695.)

Scirrhus cancer, when it extends from the stomach, is apt to involve the liver, causing its enlargement, and also occasions much pain and constitutional disturbance. Medullary cancer gives rise to similar symptoms, but is much more rapid in its progress. Colloid cancer is slower in its progress than either of the other varie-

tics, is attended with less pain and less constitutional disturbance, and is apt to involve the mesentery, and not the liver, when it extends from the stomach; ascites is also apt to be present when the disease has extended to the peritoneum or omentum.

When the body of the stomach is the seat of cancer, the cardiac and pyloric orifices remaining unobstructed, vomiting, if it occurs at all, manifests itself shortly after meals, the matters ejected being moderate in quantity, and consisting of the gastric secretions and portions of the food; and frequently the food is altered by digestion, or by some fermentative process. Fetid eructations are common. The tumor will be felt in that place occupied by the diseased part of the stomach.—When the cardiac orifice is the seat of the disease, the passage of food into the stomach is more or less interfered with, from a gradual narrowing of the lower end of the œsophageal tube, causing a sensation of uneasiness or pain at the epigastrium, which passes through to the back; and portions of food are frequently retained in the lower end of the œsophagus, from which they are ejected by eructations. The tumor will be felt at this gastric orifice.—When the pylorus is affected, and obstructive disease set up, the indications of cancer are better marked than when other parts are attacked. The pyloric orifice becoming more or less strictured, vomiting occurs some hours after meals, and the matters ejected are acid and in large quantity, and frequently contain fermented matters, *sarcinæ* blood, etc. The tumor is usually felt at the place occupied by the diseased portion, but as the stomach gradually enlarges, there will be an unusual resonance on percussion, and the tumor may descend even as far down as the right iliac fossa.

Sometimes cancer of the stomach presents no symptoms, or at least none that would refer to the organ affected. Even a tumor may be felt, and yet not be owing to cancer, but to some other disease. Again, emaciation is not always present; Napoleon Bonaparte, who had gastric cancer, was very fat when he died.

The *prognosis* of cancer of the stomach is always unfavorable; all that art has been able to accomplish is to palliate urgent symptoms. The scirrhus variety, which is the most common form of gastric cancer, is apt to prove fatal before it softens or ulcerates.

The *pathological appearances* met with will be in accordance with the advanced condition of the disease, and with the particular variety of cancer present. The stomach may be enlarged, and contain a dark-colored fluid. According to the seat of the disease, either the cardiac or pyloric orifice may be strictured. The affected part may be hypertrophied, or thickened and indurated, creaking when

cut into, and of a grayish, white, or yellowish appearance, translucent or opaque. The coats of the stomach, with the exception of the peritoneal, are often so deeply involved that they can not be recognized. Tumors are often formed in the submucous cellular tissue, and the walls of the stomach frequently present polypi, fungi, vegetations, etc., with or without ulcers. The diseased part will be, in a greater or less degree, thicker than natural, presenting an irregular internal surface, frequently ulcerated, and containing whitish or blackish fungous matter. When the cardiac orifice is affected, the odor emanating from it is often very offensive; but, if the pyloric orifice be the seat of the disease, an offensive odor is less usual, probably, from the antiseptic agency of the gastric juice on the surface of the ulcer. An examination of the adjacent abdominal organs will usually detect cancerous deposits to a greater or less extent, in some of them, as has been referred to heretofore. Under the microscope, more or less cancer cells may be detected in the diseased tissues, together with portions of fibrous tissue.

In the *treatment* of gastric cancer a proper regulation of the diet is one of the most important features. Milk is the most appropriate article of diet; though arrow-root, tapioca, animal broths, yolk of eggs beaten up with sugar and then with cold arrow-root infusion, cooked pulp of ripe fruits when they do not disagree, etc., may be used in many instances. No solid food should be taken, as it is apt to occasion pain and vomiting; and the quantity of food to be taken at a time, as well as the kind or quality, must depend upon the influence it exerts in giving rise to the above-named symptoms. When much nourishment can not be taken into the stomach, without oppressing this organ or occasioning distressing symptoms, it will have to be administered by enemata frequently repeated; and when stimulants are required, as, wine, brandy, etc., they may be added to the nourishing injections.

In the early period of the disease, occasional advantage may be derived from the following pills: Take of Chloride of Gold and Soda one or two grains, Extract of Conium thirty grains; mix together and divide into twenty pills. One of these may be taken for a dose, repeating it three times a day; it should be taken, each time, when the stomach is empty, and no food should be taken for half an hour or an hour after each dose. As a constant drink, an infusion of Viburnum Dentatum, Rumex Crispus, or Nymphaea Odorata, separately or combined, to which Hydrochlorate of Ammonia has been added, may be freely used; or a very dilute solution of Carbolic Acid.

Excessive secretion of gastric juice, or mucus, from irritation

of the stomach, may be frequently alleviated by Trisnitrate of Bismuth and Extract of Conium in pill form. It is better to avoid the preparations of Opium as long as possible on account of the constipation they produce, but when they must be used, the Opium itself will be found usually more beneficial than any of its salts.—Acidity of the stomach may be neutralized by the use of Magnesia, finely-powdered Wood Charcoal, or Lime-water.—Offensive eructations may be overcome by the use of Charcoal, Hyposulphite of Soda, infusion of Wood Soot, or, a drop of Creosote added to a gill of Mint Water, which may be divided into two or three doses.—Constipation may be overcome by purgative enemas, containing Aloes, Colocynth, Podophyllin, etc.; purgatives by mouth should not be administered until it actually becomes necessary, and then those articles should be employed that influence the large intestine only, and exert but little irritation upon the stomach. Sometimes, very dilute Nitro-hydrochloric Acid, rubbed upon the abdomen and thighs, two or three times a day, will occasion alvine evacuations.—Excessive pain, nervous irritability, and wakefulness require sedatives and narcotics, as, Conium, Belladonna, or Stramonium Extracts, or Opium, to which article we will finally be obliged to have recourse in preference to all others, in order to obtain relief. I have found considerable benefit in a few instances, by a combination of Opium and Extract of Sculleap.—I am not aware that hypodermic injections in the region of the epigastrium have been attempted in this disease, but I should judge them to be useful in allaying pain, in many instances.

HÆMATEMESIS.

Hæmatemesis, or Vomiting of Blood from the Stomach, is a symptom of no unfrequent occurrence, but is not usually of a serious nature, when idiopathic. When it occurs as a secondary symptom, its prognosis is associated with that of the primary disease.

The *causes* of gastric hemorrhage are various. It may arise from ulceration of the stomach; from congested or obstructed portal circulation; from vicarious menstruation; from cancerous disease; from a vitiated state of the blood; from aneurism, etc. Primary or idiopathic hæmatemesis is due to the state of the mucous lining membrane of the stomach, or superior portion of the duodenum, the venous capillaries of which are in a congested, enfeebled, or atonic condition.

The predisposing causes of gastric hemorrhage are, hereditary conformation, tendency to hemorrhages, mental irritability, indolence, intemperance in eating or drinking, etc. The hemorrhage may be occasioned by whatever will enfeeble or overexcite the mucous membrane of the organ, or interfere with the return of blood from the organ, as, an abuse of emetics, or cathartics; acrid or poisonous substances; blows upon the stomach; use of intoxicating or highly stimulating liquors; violent and depressing passions; cold; continued pressure on the stomach; or worms, larvæ, etc., in the stomach.

The *symptoms* of gastric hemorrhage vary somewhat according to its cause. Ordinarily, it is preceded by a sense of weight and oppression in the stomach, sometimes pain at the epigastrium, nausea, either a loss or increase of appetite, flatulence, acid eructations, anxiety, ringing in the ears, faintness or a sense of sinking at the epigastrium, pain or uneasiness in the left hypochondrium, sometimes a burning sensation, with or without distention and tenderness, sense of constriction about the chest, alternate flashes of heat and chills, cold extremities, pale and contracted countenance, palpitation, depressed pulse, etc. One or several of these symptoms are usually present; in some rare cases, the hemorrhage may come on suddenly without any premonitory symptoms sufficient to attract attention, and may prove suddenly fatal. Where the hemorrhage is secondary, it is preceded and accompanied by the symptoms usual to the malady of which it is symptomatic.—The blood, which is usually vomited up without coughing or hawking, is, dark, clotted, frequently mixed with a portion of the contents of the stomach, and sometimes appears also in the stools. The dark, grumous, or tarry-looking condition of the blood is due to the action of the gastric juice upon the hematin, and the admixture of the discharge with the secretions and contents of the stomach. The quantity raised at a time may be large or small, but, being frequently discharged at short intervals, may exhaust the patient very much; or, it may be very profuse from the first, rapidly reducing the strength of the patient. Occasionally the blood is florid and liquid. If the patient is not destroyed by the bleeding, he generally experiences more or less considerable relief from his previous disagreeable sensations.

Gastric hemorrhage from ulceration of the stomach, or from cancer of the stomach, is generally preceded by the usual symptoms of these maladies, and, in the former disease, is frequently very considerable, amounting to several pints, especially in those cases where the ulceration has extended into one of the arteries of

the stomach. When it is the result of rupture of an aneurism, it is commonly preceded by a pulsating tumor, and pain in the course of the spinal nerves; the blood, in this case, may be florid and fluid, and death occurs quickly.—When due to congested or obstructed portal circulation, it is usually preceded by pain in the right side, impaired appetite, nausea, colic, constipation, furred tongue, sallow complexion, and other signs of engorged liver, and dyspepsia from deficient gastric juice.—When occurring as a vicarious discharge, there will be amenorrhea, slight pain in the side, perhaps neuralgic pains, leucorrhea, hysteria, etc.; the discharge will manifest itself periodically, without occasioning much pallor of countenance, or any constitutional disturbance.—When associated with a vitiated condition of the blood, it is generally preceded by the symptoms common to the peculiar morbid condition, as, typhus, yellow fever, purpura hemorrhagica, scorbutus, exanthemata, etc.

Gastric hemorrhage may be *determined* from hemoptysis, by the blood being vomited and not coughed up, by the absence of cough, tickling in the throat, and bubbling sensation within the thorax, by the discharge being ordinarily larger in quantity than that from the lungs, of a darker color, thicker, and often containing some of the ingesta. In hemoptysis, the blood is frothy, bright red, is coughed or hawked up, and occurs in a succession of mouthfuls. In gastric hemorrhage, dark blood may frequently be observed in the stools. There is usually more pallor, and a greater tendency to syncope in bleeding from the stomach, than from the lungs. In cases of doubt, the lungs and the heart should be physically examined, and the general symptoms present should be carefully considered.—Blood may be swallowed when a hemorrhage from the gums, mouth, or nostrils takes place, and should it be subsequently vomited may lead to the suspicion of gastric hemorrhage; in such cases, the usual symptoms of bleeding from the stomach will be absent, and a careful examination may detect the source of the discharge.

The *prognosis* of gastric hemorrhage, when idiopathic, or vicarious, is ordinarily favorable; for we frequently observe patients who present almost a bloodless appearance, convalesce and recover. It must, however, be remembered that a primary or vicarious hematemesis, may be so profuse as to terminate fatally, and hence, the physician should always bestow attention until the more serious symptoms have been overcome. But, when the hemorrhage is secondary, the prognosis then depends upon the abundance of the

flow, the constitutional symptoms, and the nature of the disease associated with it.

The *pathological appearances* vary according to the cause of the hemorrhage. In idiopathic and vicarious bleeding, the mucous lining membrane of the stomach presents dark-red, purplish, brown, or black spots or patches of ecchymosis; and an enlarged, dilated, or injected condition of its capillaries. Rarely, signs of gastritis may be observed, with scattered patches caused by an infiltration of blood in the submucous cellular tissue. In other cases, again, the stomach will present no morbid appearance, especially when the hemorrhage was due to disease in some adjacent organ. When the hemorrhage has been profuse the whole of the stomach may be in a flaccid, dilated, and pale state. If any blood be remaining in the stomach, it will be more or less coagulated, and dark-colored or grumous. If the hemorrhage be due to ulcer or cancer of the stomach, or aneurism, the usual pathological appearances of these morbid conditions will be present. If it be due to congested portal symptom, etc., abnormal conditions of the liver, spleen, etc., will be observed.

The *treatment* of gastric hemorrhage presents two indications, viz.: to arrest the attack, and to remove, subsequently, the pathological conditions giving rise to the hemorrhage. If the discharge be primary, or, if the exact nature of its cause is not positively determined, the patient should have his feet placed in warm mustard water for some minutes, then have them dried with considerable friction, and, subsequently, if necessary, have sinapisms applied to them; after which he should be placed in a recumbent or semi-recumbent position, and be kept as quiet as possible. Dry cups, followed by a sinapism, to the epigastric region will frequently be serviceable. Internally, various agents have been administered with success, as, ten or fifteen drops of the Oil of Fireweed, or Oil of Fleabane, given on a little sugar or salt every fifteen, twenty, or thirty minutes, according to the urgency of the case; Tincture of Chloride of Iron in doses of twenty drops, in some cold water, as often as required; Solution of Perchloride of Iron; Warren's Styptic Balsam; Oil of Turpentine, etc. All the drinks of the patient must be cold, and much advantage may be derived by permitting small pieces of ice to be swallowed from time to time, until the hemorrhage ceases. In addition to these measures, when there are evident accumulations in the bowels, a purgative must be administered, and repeated, if necessary, every two or three hours; a fluidounce of Castor Oil with twenty or thirty drops of Oil of Turpentine forms an excellent purgative. In some cases, the use of saline purgatives

will be beneficial, as, Sulphate of Magnesia, Potassa, or Soda—these act as astringents and revellents, and remove the black tarry-like blood (*melana*) that may have accumulated in the intestines.

If the hemorrhage be vicarious, it is better not to endeavor to check it, unless it be very profuse; we should rather endeavor to restore the natural menstrual flow, by all the therapeutical and hygienical means employed for this purpose, as, exercise in the open air, hip baths, uterine tonics, etc. No permanent benefit can be expected until this is affected.

If the hemorrhage arises from hepatic or splenic congestion, a fomentation of Stramonium or Belladonna Leaves may be placed over the congested organ; and, internally, a combination of small doses of Podophyllin with Extract of Conium in form of pill, may be administered as often as required; this course will relieve the congestion and arrest the hemorrhage. In these cases we can hardly expect much relief from styptics, until the congested condition of the affected organs has been removed. Acidity of stomach may be relieved by Charcoal, Magnesia, or Compound Powder of Rhubarb and Potassa. For permanent cure, the hepatic or splenic affection must be properly treated.

When the hemorrhage is due to gastric ulcer or cancer, Gallic Acid, Oil of Turpentine, Solution of Perchloride of Iron, Alum with dilute Sulphuric Acid, Kino, or Catechu, etc., are among the agents that may be used to arrest the flow; adopting the means already advised in the treatment of these affections, whenever the bleeding ceases.—If the hemorrhage be dependent upon a vitiated condition of the blood, in addition to the means employed to check an excessive discharge, the proper agents must be administered to restore this flow to its natural condition, as named under Purpura, Scorbutus, etc. In malarial districts, where there is often a periodical irritability of the stomach, a pill composed of Sulphate of Quinia half a grain, Trisnitate of Bismuth three grains, Extract of Conium one grain, will be found very useful; it may be repeated, as required, every three or four hours daily.

During the hemorrhage, a total abstinence from food should be enjoined, or, if any be allowed it should be dry, not allowing too much fluid; and thirst may be assuaged by small pieces of ice held in the mouth, or iced orange-juice, or, ice-cold sulphuric lemonade. After the discharge has ceased, beef tea, gruel, rice-water, oyster soup, soft-boiled eggs, custard, buttermilk, etc., may be allowed; and if much debility be present, a careful use of ale, porter, wine whey, etc., together with the Compound Wine of Comfrey, or such other tonic as may be indicated, or suited to the case.

There are several other organic affections of the stomach, as, *Fibroid degeneration of the Pylorus, Polypus*, etc., of which, however, there are no certain methods of detecting or treating.

DYSPEPSIA.

Dyspepsia or Indigestion are the terms applied to derangements of the natural functions of the stomach, independent of any organic or inflammatory disease of that organ; though, dyspepsia may precede, and even accompany structural change. It is a very common disease, met with in all classes of society, and in every country; commencing in an insidious manner, and ultimately rendering life a burden. Although young persons may labor under dyspepsia, it is more commonly met with after the thirtieth or thirty-fifth year, or in middle life, and seems to be due chiefly to impairment or derangement of the nervous powers associated with and necessary to the digestive functions. (*See Chronic Gastritis, e*, page 699.)

The *symptoms* of dyspepsia are various, depending upon the stage of the disease, and the peculiar conditions giving rise to it, or associated with it; and, although there are a few symptoms common to all dyspeptic patients, yet, as a general rule, it will be found that scarcely any two individuals experience exactly the same group. The more common symptoms that are presented to the practitioner, are, at first, a sense of fullness, distension, or weight in the epigastrium, and a variable appetite, which is generally feeble, sometimes wholly lost, and at others voracious, or morbidly craving, and a full or hearty meal is followed by a fullness, heaviness, or pain in the epigastrium, which continues for some hours after the meal, and is accompanied with lowness of spirits or despondency. Frequently, there is a morbid desire to eat, after having already finished a meal, and the first mouthful swallowed appeases the hunger. Occasionally there is a loathing of food. With some patients, there is a *constant* uneasy feeling, weight, fullness, or pain in the gastric region. There is frequently a fluttering or sinking sensation experienced at the epigastrium, and, in many cases, pressure on this part, produces tenderness or soreness. Flatulence and acidity of the stomach are very common symptoms; so also are acid or disagreeable eructations, pyrosis, and mental depression. Indeed, it will be found that the conditions of the mind are numerous and diversified, according to the education, surrounding circumstances, and mental peculiarities of the patient, varying in every degree from a simple feeling of discon-

tent or lowness of spirits to intense unhappiness. External objects no longer appear in a state of reality; there may be an apparent inharmoniousness in everything surrounding the patient; frequently there is an undefined sense of fear and apprehension, as, a dread of sleeping alone, or of being alone, or of being from home at night, or imagined dangers from various sources, etc.; again, various diseases are often imagined to exist, as, phthisis, cardiac disease, prostatic disease, impotency, etc.; and in various other ways are these mental aberrations manifested, frequently changing the disposition, habits, and feelings of the patient, driving him into mental and physical indolence; a sense of inability to manage the most ordinary affairs of life; fretfulness and irritability; a sense of dissatisfaction with everything; fanatic extravagancies, religious frenzy, or hypochondria, etc., and very often perpetuating the disease under which he is laboring, in spite of all treatment.

There is, generally, a disagreeable taste in the mouth, especially upon rising in the morning; the tongue is covered with a whitish fur, and sometimes its papillæ are enlarged and prominent, especially toward the base of the organ; sometimes it is clean and polished, or, the center heavily loaded, with polished tip and edges; in other cases, the surface of the tongue will be more or less deeply furrowed; the body of the tongue is usually pale, sometimes natural, and occasionally redder than natural. In all gastric diseases the base of the tongue should be examined particularly. Constipation, high-colored and scalding urine, and nightmare, are also present in many cases; constipation, more especially when the gastric affection is associated with intestinal dyspepsia, or maladies of the spleen. Headache is common, especially after eating, and is frequently preceded or accompanied with chilliness, increased pallor, reduced pulse, and somnolency. Cold or acid drinks are frequently craved. As the disease progresses, cardialgia will be often experienced, also cardiac palpitation, or increased aortic pulsation, and colic pains; the pulse often becomes corded and frequent; colic pains become more violent, and occur more frequently; all the previous symptoms become aggravated; diarrhea, in which the food passes imperfectly digested, is of frequent occurrence; debility and emaciation ensue; the countenance becomes more sallow, with a wild, anxious appearance; the skin is dry and wrinkled; pains in the left side, with an inability to lie on that side, and there is generally a morbid susceptibility to cold. Heat of the stomach, aphthous ulcers of the mouth, and eruptions on the face, are by no means uncommon. Vertigo, tinnitus aurium,

double-vision and other derangements of vision, acute tenderness of the scalp, etc., are often complained of.* Although one patient will scarcely present all the symptoms above enumerated, yet several of them are almost always associated, and, among a num-

* In a small work, entitled "The Dyspeptic's Monitor," etc., by S. W. Avery, M. D., New York, 1830, are the following remarks, which are as worthy of attention at this time as at the period of their publication. Dr. Avery divides derangements of the digestive organs into three species. He considers the *first* species to "Consist in an enfeebled condition of the stomach, which secretes a preternatural quantity of highly acid fluid, unfit for the process of healthy digestion. The prominent symptoms are, incessant, dull headache, especially aggravated after eating, flatulence, an uneasy gnawing sensation in the stomach when empty, usually mistaken for hunger, heart-burn, acid eructations and belching, especially after eating, profuse flow of saliva into the mouth, tongue lightly coated, and an unpleasant taste in the mouth in the morning. There is sometimes thrown up a short time after eating, especially the breakfast, a considerable quantity of limpid, sour fluid, so acrid as to give a scalded appearance to the tongue and throat; sometimes it is mixed with bitter or oily matters, but rarely with any of the food taken. If indigestible food, as fatty meats, or a considerable quantity of any fluid be taken at meals; for some hours after, the distress is increased, all the symptoms aggravated, and a general feverish condition induced. Notwithstanding all this disturbance in the stomach, the bowels often continue nearly regular, and the action of the liver not seriously deranged, particularly in such as have frequent acid eructations. This species is often attended with a train of symptoms which pass for nervous, and which are only to be overcome by *correcting the acidity of the stomach*. A part of this acid no doubt arises from the ingesta undergoing the acetous fermentation during digestion; but much the greater part of it is a secretion of the stomach,—a vitiated gastric juice, caused by indigestible or improper food being taken into an enfeebled stomach.

"The *second* species is marked by hepatic derangement, combined with imperfect digestion. This form is apt to occur, or become aggravated, during summer, and to remit as cold weather approaches. Its leading features are connected with bilious disorder, as, remarkable depression of strength with languor and listlessness, especially on rising in the morning; bitter, disagreeable taste in the mouth; yellow fur on the tongue; torpid and irregular bowels; high-colored urine; restless, feverish nights, and progressive emaciation. The patient often complains of vague pains shooting in various directions, sometimes in the shoulders, back of the neck, and at other times in the sides or pit of the stomach, and a sense of weariness in all his limbs; almost constant aching in the back and loins, with a numbness of the right side and arm, or a burning sensation at the epigastrium. The complexion is often of a dingy hue, and the eyes occasionally have a yellow tinge. The state of his strength is very uncertain and variable, sometimes he can scarcely lift up his hand, and soon after he will walk a mile without much fatigue. All his complaints are greatly aggravated by eating, and he obtains so much relief from fasting, that he dreads the return of meals, which invariably add to his mental, as well as bodily suffering, by plunging him into gloom and melancholy, till finally his temper is rendered so irritable and impatient that no fortitude can repress its sallies.

"The *third* species depends upon a morbid sensibility or irritability of the inner

ber of patients taken in the aggregate, the greater part of these symptoms, if not all of them, will be encountered.

Usually, there are associated with dyspepsia certain prominent symptoms which should receive particular attention, as they fre-

surface of the stomach and bowels, with more or less hepatic derangement. It presents itself in two forms, either with or without *marked* symptoms of indigestion. In the former, it often goes to the extent of painful digestion, especially on taking any stimulant article; in some cases, any solid substance, as a crust of bread, will bring it on, so that the patient is obliged to confine himself to light fluid nourishment, in order to avoid the gastric distress, the tormenting headache, the nervous agitations, the palpitations, and finally, the faintness, nausea, and vomiting that is apt to ensue on the least error of diet. When the disease arrives at this stage, the head is seldom free from pain; solid food is rejected without having undergone the least change, after remaining for hours in the stomach; the bowels become torpid; the complexion dingy; the strength and flesh waste rapidly, and the nights are restless, feverish, and disturbed by frightful dreams. The function of the liver is generally much deranged, producing pain in the side, slight, hacking cough, a sense of weariness or pain in the back, loins, and limbs, listlessness, with dejection of mind and gloominess. A most distressing train of nervous symptoms is often connected with this form of the disease. The most trifling occurrence frightens and agitates the patient, produces palpitations, and shows his whole nervous system to be acutely sensible. His bowels also become so morbidly irritable as to be acted on violently by the smallest quantity of cathartic medicine, producing pain and uneasiness, which induces the patient to delay its repetition as long as he possibly can.

"The other form of this species is the most melancholy of all these derangements. It is usually known by the names of low spirits, hypochondriasis, melancholy, etc., and is extremely various in its character and forms. Indigestion seldom forms a prominent feature of the disease; often, indeed, there are few or no symptoms of such derangement present, in which case the true seat and nature of the disease may be wholly overlooked. The persons most subject to this form are generally past the meridian of life, and such as have been engaged in active business, particularly in hot climates. Flatulence, eructations, sense of distension and weight at the stomach after eating, irregular bowels, etc., are present in some cases; in others, there are no indications of bad digestion, or at least very slight ones. When they do exist, however, they are apt to be overlooked in anxiously attending to the sympathetic affections of other parts. In some instances the head is affected with giddiness, and confusion of ideas, ringing in the ears, and indistinct vision. In others, the action of the heart becomes exceedingly irregular, throbbing, and beating violently against the side, now and then intermitting, and occasioning great distress and anxiety. Sometimes there is severe smarting and pain in voiding the urine, which is often scanty, turbid, and high-colored, then again abundant and colorless. But it would be fruitless to attempt to give a description of all the varied forms of this Protean disease; one character, however, is common to them all, and that is the most dreadful mental dejection, and a disposition to magnify every unpleasant feeling, and to look upon their complaints as incurable and fatal. The bile in the worst forms of this species is often greatly altered from its healthy condition; it becomes thick, ropy, and tenacious, like bird-lime, and so acrid as to irritate and excite excessive pain in the parts it passes over."

quently act as indices to the character of treatment that should be pursued. Thus, with some patients an excessive acidity of the stomach, manifested by a thick white coat upon the tongue, unpleasant taste in the mouth, in the morning after a night's sleep; again, eructations of a fetid or acid character may be present; or excessive flatulency; severe pain in the epigastric region, and this may be continuous, or manifest itself either shortly before or soon after a meal; constipation of an obstinate character may be a prominent symptom, but this is generally due to intestinal affection. With many patients, the dyspeptic symptoms present themselves only after having partaken of certain articles of food, as, albuminous, saccharine, amylaceous, oily, alcoholic, etc.; or, again, the want of one of these particular articles may give rise to the digestive derangements. I am acquainted with a gentleman with whose stomach every article of diet agrees, save custard; the instant the first teaspoonful reaches his stomach, he is attacked with a diarrhea that almost always requires medical aid before it can be removed. This has proved a source of much annoyance to him, especially when away from home, and when, forgetting himself, he has swallowed a spoonful of custard, he has been invariably compelled to leave the table immediately.

In the examination of patients laboring under the symptoms above named, the physician must be very careful to avoid jumping at conclusions; he must remember that similar symptoms are common to other gastric affections, and that these affections may be complicated with dyspepsia either as a cause or a result. Great care and patience is, therefore, required in these investigations.

Dyspepsia *may arise* from abnormal conditions of the nervous system, as well as of the blood, and, indirectly, by the various conditions that affect the nutritive processes in the body. An unhealthy condition of the nervous system, and especially of those nerves more directly associated with the gastric functions, must, necessarily, impair these functions to a greater or less extent. Unhealthy blood, due to any cause, must necessarily give rise to unhealthy secretions, and impaired nervous power; and, if the stomach be the organ more especially influenced from this cause, some form of indigestion must be the inevitable result. Again, between the stomach and the various organs of the body there exists an intimate sympathetic relation, so that when one or more distant organs become functionally or organically affected, it is by no means uncommon to witness an impairment of the digestive powers. Thus, in asthma, gout, diabetes, several cutaneous maladies, cerebral, cardiac, hepatic, or renal disease, symptoms of indigestion are often observed, and which can

only be removed by the cure of the primary affection,—this imperfection or perversion of the digestive function is not generally included under the head of Indigestion, but has been referred to primary mal-assimilation.—Habershon states that dyspepsia arises, “1. From abnormal condition of the gastric mucous membrane and its secretion; 2. From the muscular movements being impeded; 3. From the state of the vascular supply; 4. From the condition of the nervous system; and, lastly, 5. From the character and changes which take place in the food. Several of these causes of dyspepsia may be combined; some lead to disease of a very transient form, others are irremediable.”

Among the causes producing dyspepsia, a very prominent one is, the ingestion of a large amount of food, hastily and imperfectly masticated, and followed by undue mental or physical exertion, as, is apt to be the case with merchants, artists, and others of sedentary occupations. Excessive action either of mind or body, should always be avoided for some time previous to, as well as after a meal; to insure healthy digestion and tone of the stomach, both the mind and the body should be properly and regularly exercised, with appropriate intervals of rest or recreation. Dyspepsia is especially common to those who eat hastily, and in large quantity, as, among merchants, travelers, and hotel-boarders. To witness the major portion of American meals, and especially at public places, one would suppose that it was a matter of no interest how food was eaten, so it became safely lodged in the stomach. A stranger to the habits of this country, on witnessing a meal on a steamboat, or at a hotel, would be led to believe either that the partakers thereof never had a full meal before; that they were in constant dread of a visit from the sheriff; that they were eating on a wager, the first one from the table to be winner; or, that the meal was so obnoxious a task, that every one endeavored to hasten through it as rapidly as possible, pouring soups, fish, meats, custards, pies, liquors, nuts, oranges, raisins, etc., into the stomach, *en masse*, without regard to quantity, quality, or suitableness for the digestive organs.

Dyspepsia may likewise be produced by certain, long-continued habits, as, the use of powerful stimulants, alcoholic liquors, high-seasoned dishes, too frequent use of warm fluids, tobacco, late hours, excess in venery, masturbation, sedentary life more especially when conjoined with excessive brain-work, indolence, mental depression, great anxiety, excessive muscular exertion, and indeed by anything that will impair or destroy the sensibility of the stomach, or diminish its nervous energy. Frequently the disease will depend upon some affection of the spinal cord. And I have no doubt but that the

foundation of the disease is laid, more frequently than is dreamed of, by the constant use of water passing through lead pipes, together with that of the *trasí* so generally sold in our cities under the name of "milk."

As already remarked, in the *diagnosis* of dyspepsia, great care should be taken to ascertain whether the symptoms are due to this affection simply, or to some other gastric malady; also, whether a disease of some other organ or organs exists, that may mask or aggravate the dyspeptic symptoms; and whether the indigestion is independent of such affections, or, is either a cause, or a result of their presence.

The urine of dyspeptic persons usually presents one of three kinds of deposit, that may exist separately, together, or alternately at various intervals. They are, 1. Oxalate of Lime, either in crystals or dumb-bells, and are apt to be associated with flatulency, debility, fatigue on slight exertion, cardiac palpitation more marked and obstinate than in other forms of dyspepsia, tendency to emaciation, sleeplessness, mental depression, irritability, anxiety, uneasiness or pain in the lumbar region, tendency to boils or scaly eruptions, frequent evacuations of the bladder; and a fancied or real deficiency of sexual power; it is a common deposit among those dyspeptics who have been masturbators. 2. Urate of Soda, of Ammonia, or Uric Acid, may be the passing consequence of an excess at table, or may result from habitual high living, a gouty or rheumatic tendency, etc.; when abundant, there is apt to be a grave affection of the liver. The dyspepsia in which these deposits are in excess is usually associated with furred tongue, sallow skin, hepatic torpor, constipation, and heavy or disturbed and unrefreshing sleep. 3. Triple Phosphates are usually present in cases associated with mental despondency, general debility, and a state of depressed nervous energy. A solution to the presence of these deposits may also be found in the character of the food and the manner in which it is acted upon by the digestive process.

In most cases of simple dyspepsia the *prognosis* is favorable; the earlier the case is brought under treatment the greater are the chances for cure, provided the patient will strictly follow directions. In long-standing cases, structural lesions of the digestive organs are apt to occur, and in such instances, as well as in those complicated with other diseases, permanent cures are rarely effected; palliation of urgent symptoms is generally the most that can be promised in such cases.

The *treatment* of dyspepsia in its early stage is a simple matter, requiring no medicine, but merely an attention on the part of

the patient to proper hygienical measures. Unfortunately, however, patients are rarely found who will subject themselves to the necessary hygiene, or deny themselves the pleasures of the table, as long as their symptoms do not compel them to do so, and when they are thus compelled, their disease has usually made such inroads that medicines are more apt to prove palliatives instead of curatives.

Brinton, in remarking upon the use of remedies, and the cure of disease by nature and diet, concludes thus: "Even in dyspepsia, the palliative effects of drugs are far too precious to be dispensed with. While, as regards their less measurable tonic and alterative effects, those who have witnessed their influence among the dyspeptic poor, and against all the terrible concomitants—scanty food, foul air, excessive toil, and intemperance—dyspepsia here possesses, must know that it would be a mockery to restrict this important class of our patients to regimen or *hygiene*. To tell an idle and wealthy dyspeptic that his malady might be cured without drugs, would be a hardy statement, though sometimes a true one. But to recommend dyspeptics in general to dispense with all medicines, would be not only illogical, but absurd; indeed, considering the circumstances of most of our patients, even in the affluent classes, scarcely less foolish or cruel than to withhold a rope from a drowning man, and to advise him to save himself by building a boat."—Yet, notwithstanding these remarks, we must be very careful not to administer active remedies, unless they are positively and distinctly indicated; for the injudicious administration of medicines has permanently ruined many dyspeptic stomachs. Administer no active agent, unless with the view of effecting a required indication; and if this indication is not known, omit the medicine and spare the patient's stomach. It is much better to trust to hygiene and the resources of nature than to throw drugs blindly into the stomach. The practice of medicine does not consist in enormous doses of drugs, to ascertain how much a patient may take and recover, but in curing any disease with the least medicine possible. He is the best physician who can cure his patients without medicines; but, strange to say, the public have, unfortunately for themselves, formed a different opinion.

The therapeutical measures to be employed will greatly vary according to the peculiarity of the symptoms and the complications present. The principal object in simple dyspepsia is to impart healthy action to the coats of the stomach, and restore nervous power to this organ, and for this purpose there are numerous agents—that may be employed in various combinations, as, Aletri-

din, Hydrastin, Alcoholic Extract of Nux Vomica, Strychnia, Black Alder Bark, Witch Hazle Bark, Solomon's Seal, Colombo, Gentian, Compound Tincture of Tamarac Bark, Compound Pills of Eupurpurin, etc. All other means are merely auxiliary, instituted to meet certain urgent symptoms. We will find, however, according to the condition of follicular atrophy of the gastric mucous membrane, anemia, debility or irritability of the stomach, acidity, etc., that these agents will require to be variously combined in order to meet the great variety of cases that will be encountered,—certain combinations being of great efficacy in some cases, and of no value in others.

Among the combinations that I have found more generally useful are the following: 1. Take of Hydrastin, Ptelein, each, forty-eight grains, Extract of Belladonna six grains, Alcoholic Extract of Nux Vomica four grains, mix thoroughly and divide into forty-eight pills. One of these pills is a dose, and may be repeated three times a day. At the same time, provided no gastric acidity be present, an infusion of equal parts of Solomon's Seal Root and Black Alder Bark may be used freely. 2. Take, of Bromide of Potassium forty grains, Soluble Hydrastin twenty grains, Strychnia one grain, Alcoholic Extract of Aletris twenty grains; mix, and divide into twenty pills, to be taken in the same manner as the preceding. 3. Take of Oxide of Silver eight grains, Alcoholic Extract of Aletris twenty-four grains, powdered Colombo a sufficient quantity, mix, and divide into twenty-four pills, to be taken as the preceding. 4. Take of Citrate of Iron and Strychnia forty grains, Extract of Quassia, Alcoholic Extract of Aletris, Soluble Hydrastin, each, twenty grains; mix, and divide into twenty-four pills to be taken as the preceding. As a general rule these pills will be found efficacious either with or without auxiliary measures, according to urgent symptoms or complications.

Instead of the infusion of Solomon's Seal and Black Alder referred to above, I frequently employ, and with most excellent results, the following: Take of White Indian Hemp Root, Colombo, Sassafras, each, three ounces, Quassia one and a half ounces, Prickly-ash berries six drachms; mix, and form an infusion. It may be taken in half tablespoonful doses three or four times a day, and will be found useful in cases with thick white coat on the tongue, body of the tongue pale, and epigastric pain. In advanced life, or in cases where there is great enfeeblement of the digestive powers, with loss of appetite, constipation, enfeebled pulse, paleness of the body of the tongue, as well as in anemic cases, spiced Wine Bitters, Compound Tincture of Tamarac, moderate use of stimu-

lants, with some preparation of iron and very nutritious diet, are among the agents that may be employed; being very careful, however, not to advise alcoholic stimulants among reformed inebriates.

In long-standing cases, or in strumous habits, I have found my original Iodine Pill to be very useful, thus: Take of Iodine twelve grains, Sulphate of Morphia three grains, Burnt Sponge, (or Leptandrin) twenty-four grains, Extract of Liquorice (or Alcoholic Extract of Aletris) a sufficient quantity to form into a pill mass; mix, and divide into twenty-four pills, of which one may be given every night and morning. In similar cases, attended with hepatic disease, constipation, nervous debility, etc., I have found the following very useful: Take of Strychnia one grain, Iodine seven grains, Podophyllin five grains, Extract of Belladonna two grains, Alcoholic Extract of Black Cohosh twenty grains; mix, and divide into twenty pills, of which one may be taken three times a day.—In atonic dyspepsia, attended with much nervous debility, Strychnia, Citrate of Iron and Strychnia, Phlorydzine, Sulphate of Quinia, Salicin, Lactate of Iron, and Ammonio-citrate of Iron, have been variously employed with advantage; the iron preparations are, however, contra-indicated in plethoric conditions of the system, and where there is an excess of uric acid or urates in the urine. The following will be found very useful: Take of Phlorydzine one drachm, Soluble Pyrophosphate of Iron one scruple, Glycerin four fluidounces, Aromatic Spirit of Ammonia two or three fluidrachms; mix. The dose is a tablespoonful three times a day.—Several cases of dyspepsia with hypochondria have been cured by tablespoonful doses, three times a day, of a mixture composed of Fluid Extract of Leptandra, Fluid Extract of Ptelea, Fluid Extract of Black Cohosh, each, half a fluid ounce, Fluid Extract of Poke, two fluidrachms, Brandy one pint.*

In nearly all cases, counter-irritation along the upper half of the spinal column, or even along its whole length, will be found exceedingly useful. And for this purpose I prefer the Compound Tincture of Camphor; it must be gently rubbed upon the part once or twice a day, so as to produce a moderate burning sensation, and which sensation will be present during the day or whenever the patient exercises or becomes warm. If too severe, it should not be applied so frequently. Unless this sensation is produced the article will be of no benefit. It may also be employed

* In cases where Fluid Extracts are named, it must be remembered that Essential or Concentrated Tinctures, are all identical, being only different names for similar preparations.

in cases associated with irritation of the spinal cord. Sometimes, dry cupping, firing, etc., will be useful where there is tenderness along the spinal column,—applying these over the tender points.—Emetics are rarely necessary in dyspepsia, except for the purpose of removing offending matters, excess of food, etc., from the stomach, to arouse a torpid liver, or, occasionally, to give a shock to the nervous system, and render the action of other medicines more effectual; but, as a general rule, I am opposed to the exhibition of emetics in this disease.

An attention to hygiene is always necessary, maintaining the skin, bowels, and kidneys in a normal condition, by the means heretofore referred to in the Introduction. Frequent bathings will be found very important. Moderate exercise daily, should be advised; and as to diet, the patient should be allowed to eat moderately of *anything that agrees with his digestive organs*, or, that is of easy digestion, and will not produce uneasiness or pain in the stomach, acidity, flatulency, constipation or looseness, etc., being careful to *masticate the food well before allowing it to pass into the stomach*. Indeed, I have cured many cases of dyspepsia by simply placing the patients upon a meat diet, directing them not to swallow any of it, but to continue the mastication of each mouthful until it has disappeared; in this manner the food becomes thoroughly masticated and, as it were, spontaneously passes into the stomach.* It is necessary that the patient should refrain from any kind of bodily or severe mental exercise for at least half an hour before meal-time, especially before dinner or the principal meal,—even walking should be avoided as much as possible—he should compose and thus, as it were, prepare his stomach for the meal. And after the meal, no bodily or mental exercise should be attempted for at least one hour afterward; this course will favor digestion, give tone to the stomach, impart strength to the system, and eventually obviate dyspeptic costiveness. Dyspeptics should always stand, sit and lie down in an erect position,

*I have known several instances where dyspeptic and other invalids were positively cured by the following course: for breakfast a cracker or two and some pure milk; the same for dinner, with, perhaps, a similar lunch between these meals,—the object being to avoid placing much food into the stomach during the hours when physical or mental labor is required. After finishing the business of the day, a hearty meal is made at supper, and in three or four hours after, the person retires to sleep. Making the last meal of the day, the principal one, is not exactly in accordance with the views generally entertained upon this matter, yet I have, nevertheless, known it to be productive of immense benefit; one gentleman of my acquaintance has pursued it for years; he is engaged in active business, and finds great advantage from it in every respect.

so as not to confine the stomach too much by pressure from the surrounding parts. Cheerfulness and cheerful society during exercise, at meals, etc., are important accompaniments to the dyspeptic. Great or constant mental labors must be avoided.

In those instances where the dyspepsia is the result of other diseases, or is complicated with them, they must be treated the same as if the dyspepsia were absent. But we must be very careful in our diagnosis, as, hysteria, hypochondria, cardiac palpitations, and apparent lung maladies, are often the result of a sympathetic re-action of the stomach disease upon other organs. Again, the urine should be carefully examined in all cases of dyspepsia, as it is frequently the case that the stomach symptoms are wholly due to disease of the kidney.

When dyspepsia has advanced somewhat, it is usual to find it associated with certain unpleasant symptoms, which are often so prominent as to demand special treatment; as these symptoms may also exist where there is no dyspepsia, I will now refer to them separately, giving the measures that may be employed for their removal or palliation, according to circumstances. And although many symptoms are referred to, and many remedies named, it must be remembered *that the superiority and success of the practitioner depends upon a skillful selection and combination of these agents, calculated to benefit at the same time, the dyspepsia and its prominent symptoms, without rendering them bulky, offensive to the taste, unpleasant in action, and without keeping the stomach constantly loaded with drugs.*

Excessive secretion of mucus is usually the result of a diseased state of the mucous follicles, which pour out an abundance of mucus, often combined with an excess of gastric juice. Should vomiting be associated with the symptoms indicating this condition, the neutral mucus, and the acid gastric juice may be determined by the usual chemical and microscopical tests. The principal *symptoms* in this form of dyspepsia are, deficient appetite or anorexia, a feeling of weight and distension immediately after taking the smallest amount of food, pain between the shoulders, tongue coated with a thick white layer of mucus, a constant bad taste in the mouth, flatulency, acrid eructations, and cold feet. The breath is usually fetid, sometimes there is nausea, constipation is common, though the bowels in some rare cases may be regular, and occasionally diarrhea may be present. Vomiting may also exist, and, when not mixed with gastric juice, the fluid ejected is insipid, clear, and glairy, somewhat resembling white of egg; it may be

mixed with the food, but more generally is discharged alone, and especially in the morning before breakfast. The disease is commonly met with among persons whose nervous systems are greatly impaired, as, drunkards, overworked and poorly fed persons, hard students, etc. This catarrhal state of the stomach is usually associated with an inflamed or congested condition of the gastric mucous membrane, which is frequently caused by a similar state of the portal system.
